The protein and lipid composition of eukaryotic plasma membranes is highly dynamic and regulated according to need. The sphingolipid-responsive Pkh kinases are candidates for mediating parts of this regulation, as they affect a diverse set of plasma membrane functions, such as cortical actin patch organization, efficient endocytosis, and eisosome assembly. Eissomes are large protein complexes underlying the plasma membrane and help to sort a group of membrane proteins into distinct domains. In this study, we identify Nce102 in a genome-wide screen for genes involved in eisosome organization and Pkh kinase signaling. Nce102 accumulates in membrane domains at eissomes where Pkh kinases also localize. The relative abundance of Nce102 in these domains compared with the rest of the plasma membrane is dynamically regulated by sphingolipids. Furthermore, Nce102 inhibits Pkh kinase signaling and is required for plasma membrane organization. Therefore, Nce102 might act as a sensor of sphingolipids that regulates plasma membrane function.

Introduction

The plasma membrane is highly dynamic and crucial for communication of cells with their environment. It transduces numerous extracellular signals and transports molecules in and out of the cell. To accommodate these diverse tasks, it is highly organized, and plasma membrane processes are tightly coordinated, both spatially and temporally (Simons and Toomre, 2000; Anderson and Jacobson, 2002; Simons and Vaz, 2004). How the abundance of most lipids and proteins in the plasma membrane is regulated is largely unknown.

In the yeast *Saccharomyces cerevisiae*, the plasma membrane is laterally organized into spatial domains that have different protein and lipid composition. One type of domain harbors several integral membrane proteins, such as the arginine transporter Can1 and members of the Sur7 family of proteins and was accordingly termed membrane compartment occupied by Can1 (MCC). MCCs were suggested to contain a distinct lipid composition enriched in ergosterol, as visualized by staining with filipin, a fluorescent marker binding this lipid (Malinska et al., 2003; Grossmann et al., 2007).

Yeast mother cells possess 25–45 MCCs that can be visualized as discrete foci in the plasma membrane. MCCs are mutually exclusive with a second domain, marked by the plasma membrane ATPase Pma1, termed membrane compartment occupied by Pma1 (MCP; Malinska et al., 2003, 2004). The organization of the plasma membrane in distinct spatial domains is at least in part mediated by large protein complexes termed eissomes (Walther et al., 2006). Eissomes lie underneath each MCC forming a punctate, distributed pattern in the cell cortex. When the gene encoding the major eisosome component Pil1 is deleted, MCCs and all remaining eisosome proteins investigated so far coalesce into one or a few punctae per cell (Walther et al., 2006; Grossmann et al., 2007). In addition to concentrating at such eisosome remnants, a significant fraction

of MCC transmembrane proteins, such as Sur7, localizes uniformly in the plasma membrane. Similarly, the ergosterol marker filipin loses its normal punctate eisosome localization in Δpil1 cells, distributes more evenly over the plasma membrane surface, and enriches at eisosome remnants (Grossmann et al., 2007).

One possible function of MCCs and eisosomes is to regulate protein and lipid abundance by sorting them into distinct, spatially separated pools where they are stabilized or from which they can be endocytosed selectively. Consistent with this notion, disruption of MCCs leads to increased turnover of some proteins normally localized there (Grossmann et al., 2008). The precise molecular function of eisosomes is still unclear, but it was suggested that they regulate sites of endocytosis based on their colocalization with endocytic intermediates visualized by the lipophilic dye FM4-64 and a hexose transporter GFP fusion protein (Walther et al., 2006). A clue of how eisosomes might be regulated is provided by the discovery that Pkh kinases localize at eisosomes and that Pil1 and Lsp1 are Pkh kinase substrates (Zhang et al., 2004; Walther et al., 2007; Luo et al., 2008).

Pkh kinases regulate physiology and plasma membrane functions such as actin patch organization, endocytosis, and eisosome assembly (Inagaki et al., 1999; Sun et al., 2000; Friant et al., 2001; deHart et al., 2002; Liu et al., 2005; Grosshans et al., 2006; Daquinag et al., 2007; Luo et al., 2008). These responses are mediated by their targets, including Ypk1 and Ypk2 (homologues of the mammalian serum glucocorticoid kinase), Sch9 (homologue of human AKT kinase), Pkc1 (atypical protein kinase C), and myosin-I. In addition, Pkh kinase phosphorylation of Pil1 regulates the assembly state of eisosomes (Walther et al., 2007; Luo et al., 2008).

Pkh kinases are regulated by sphingoid long chain bases such as phytosphingosine (PHS) and dihydrosphingosine, which are precursors in sphingolipid synthesis (Zhang et al., 2004). However, it is not known how Pkh kinases sense and respond to long chain bases. Pkh kinases and several other kinases of the signaling module are regulated by levels of long chain bases in vitro, but whether this is relevant in vivo and whether it is the only way to control Pkh kinase activity is not clear (Zhang et al., 2004; Liu et al., 2005).

In this study, we visually screened for genes that affect eisosome organization either directly or through altering Pkh kinase activity. We identified the transmembrane protein Nce102 as part of the sphingolipid–Pkh signaling network. Our functional experiments suggest that Nce102 might act as a sphingolipid sensor that modulates Pkh kinase activity to regulate plasma membrane organization and function.

Results

Nce102 is required for normal eisosome organization

To identify genes required for eisosome assembly and organization, we screened by fluorescence microscopy a systematic gene deletion collection into which we introduced GFP-labeled cells (right) are shown. [c] Number of eisosomes per mother cell [left], cytoplasmic Pil1-GFP fluorescence [middle], and Pil1-GFP fluorescence per eisosome [right]. Error bars indicate SD. Bar, 5 µm.
NCE102 MEDIATES SPHINGOLIPID SIGNALING

Fröhlich et al.

...characterized by fewer eisosomes, increased cytoplasmic Pil1-GFP, and little change in the size of remaining eisosomes. In addition, several hits (YMR031C, YMR086W, and MSC3) are good candidates for genes encoding previously not recognized eisosome components because they localize in a punctuate pattern at the cell periphery similar to eisosomes, and at least Ymr031c and Ymr086c were copurified with Pil1 (Huh et al., 2003; Grossmann et al., 2008; Deng et al., 2009).

In this study, we focused on Nce102 because it is the only hit in our screen previously found as a transmembrane plasma membrane protein (Cleves et al., 1996). To confirm the role of Nce102 in eisosome formation, we investigated the localization of Pil1-GFP in \( \Delta \text{nce102} \) compared with wild-type cells. Consistent with the systematic genome-wide screen, confocal images showed a clear reduction of Pil1 fusion protein (Pil1-GFP; Fig. S1 a; Tong et al., 2001). To determine the effect of individual mutations on eisosomes, we grew the library in 96-well plates to mid-log phase and imaged cells with an automated microscope. Visual inspection of the images led to identification of 88 genes that affect eisosomes (Fig. 1 a).

To obtain quantitative data for the identified mutants, we collected confocal images and quantitated the number of eisosomes per cell, the cytosolic fluorescence signal representing unassembled Pil1-GFP, the integrated fluorescence on the cell surface, the size of individual eisosomes, and the percentage of cell surface covered with eisosomes (Fig. S1 a). The relative values for these parameters were used to cluster the genes according to the similarity of their phenotypes (Fig. S1 b).

For example, deletion of genes encoding subunits of the NatC complex involved in N-terminal protein acetylation (MAK3, MAK10, and MAK31) showed a similar phenotype characterized by fewer eisosomes, increased cytoplasmic Pil1-GFP, and little change in the size of remaining eisosomes. In addition, several hits (YMR031C, YMR086W, and MSC3) are good candidates for genes encoding previously not recognized eisosome components because they localize in a punctuate pattern at the cell periphery similar to eisosomes, and at least Ymr031c and Ymr086c were copurified with Pil1 (Huh et al., 2003; Grossmann et al., 2008; Deng et al., 2009).

Nce102 is required for membrane organization

Eisosomes organize MCCs, and mutation of PIL1 results in mislocalization of all tested MCC components (Walther et al., 2006; Grossmann et al., 2007, 2008). Because NCE102 deletion results in a twofold decrease of eisosome number per mother cell and concomitant increase of cytosolic signal (Fig. 1 c).

Figure 3. Nce102 localizes to both MCC and non-MCC domains in the plasma membrane. (a) Images from cells expressing Nce102-GFP (left; green in overlay) and Sur7-mars (middle; red in the overlay) are shown. (b) Intensity profiles of Nce102-GFP and Sur7-mars along the plasma membrane. (c) Images from cells expressing Nce102-GFP (left; green in overlay) and Lsp1-mars (middle; red in the overlay) are shown. Boxes indicate the area magnified in the bottom panels. (d) Intensity profiles of Nce102-GFP and Lsp1-mars along the plasma membrane. (e) Pil1 is required for normal Nce102 distribution. Wild-type (left) and Δpil1 (right) cells expressing Nce102-GFP are shown. Arrows highlight eisosome remnants. Bars, 5 µm.

Nce102 is required for membrane organization

Eisosomes organize MCCs, and mutation of PIL1 results in mislocalization of all tested MCC components (Walther et al., 2006; Grossmann et al., 2007, 2008). Because NCE102 deletion...
has a strong effect on eisosomes, we asked whether NCE102 is also required for plasma membrane organization. Indeed, compared with wild-type cells in which the MCC marker Sur7-GFP was organized in distinct domains, Δnce102 cells showed only few clusters and more uniform localization of Sur7-GFP throughout the plasma membrane (Fig. 2 a). Furthermore, we observed a consistent but less pronounced phenotype on the MCP marker Pma1, which localized more uniformly in Δnce102 cells compared with its normal localization in structured plasma membrane domains (Fig. 2 b).

Next, we asked whether Nce102 influences the formation of endocytic intermediates formed as foci at eisosomes by using the lipophilic tracer FM4-64 (Vida and Emr, 1995; Walther et al., 2006). FM4-64 foci formed after short chase periods of ~1 min and colocalized with eisosomes in both wild-type and Δnce102 cells (Fig. 2 c). However, when we quantitated the number of foci, we found their number greatly reduced in Δnce102 cells (median = 1 foci/cell; Fig. 2 d, right) compared with wild-type cells (median = 4 foci/cell; Fig. 2 d, left). Together, this shows that normal plasma membrane organization requires Nce102.

**Nce102 localizes to the plasma membrane at MCC**

To answer how Nce102 functions, we first investigated its subcellular localization. In agreement with a recent study that identified Nce102 as an MCC component, we found Nce102-GFP localizing in the plasma membrane and accumulating in foci reminiscent of MCCs (Fig. 3 a; Grossmann et al., 2008). This notion was further confirmed by colocalization of Nce102 with plasma membrane markers but not, for example, with cortical ER markers (unpublished data).

To test whether Nce102 foci are MCCs, we investigated their localization in respect to Sur7 tagged with the red fluorophore RFP-mars (Fischer et al., 2004), an MCC marker. Nce102 foci completely overlapped with Sur7-marked MCCs (Fig. 3 a and b) with significant levels of Nce102-GFP also diffusely localized in the remainder of the plasma membrane. As MCCs are membrane domains located over eisosomes, we additionally investigated Nce102-GFP localization in respect to eisosomes marked by Lsp1-mars and found that Nce102-GFP foci and eisosomes colocalize perfectly (Fig. 3 c and d). Because Nce102 is a multipass transmembrane domain protein, it is most likely located in the MCC and partially in the remainder of the membrane.

One hallmark of proteins localizing to eisosomes or MCCs is that they collapse to one or a few eisosome remnants in Δpil1 cells (Walther et al., 2006; Grossmann et al., 2007). Indeed, Nce102-GFP localization in Δpil1 cells also closely resembles that of MCC proteins such as Sur7. Most of Nce102-GFP localizes to one or a few eisosome remnants in Δpil1 cells, whereas the remaining portion shows a uniformly distributed signal throughout the plasma membrane (Fig. 3 e).

**Nce102 acts negatively on Pil1 phosphorylation**

Because eisosome organization is sensitive to Pil1 phosphorylation, we expected to find genes in our screen that directly affect the architecture, assembly, or stability of eisosomes and genes involved in signaling that modifies Pil1 phosphorylation. In fact, the Δnce102 phenotype on Pil1-GFP localization closely resembles the phenotype of pil1(4D) mutant cells, bearing a phosphomimicking mutant of Pil1-GFP in which four residues that are phosphorylated in the wild-type protein are mutated to aspartate (S45D, S59D, S230D, and T233D; Fig. 1 b and Fig. S4 c; Walther et al., 2007).

Therefore, we tested genetically whether Nce102 acts on eisosomes by altering Pil1 phosphorylation that could then indirectly modulate eisosome assembly. If Δnce102 effect is mediated by phosphorylation, we expect that a pil1(4A)-GFP mutant in which four residues that are required for the effect of Pkh kinases on eisosome assembly are changed to alanine (S45A, S59A, S230A, and T233A; Walther et al., 2007) blocks the effect of NCE102 deletion. However, if Nce102’s effect on eisosomes is independent of Pil1 phosphorylation state, we expect to see similar effects of Δnce102 on wild-type Pil1 and pil1(4A).
Indeed, pil1(4A)-GFP localization was indistinguishable between Δnce102 and wild-type cells, showing slightly more eisosome assembly at the plasma membrane compared with wild-type Pil1 (Fig. 4b). Therefore, pil1(4A) is epistatic to Δnce102. Because Pil1 needs to get phosphorylated on residues mutated in pil1(4A) to develop the Δnce102 eisosome phenotype, we conclude that Nce102 acts upstream of Pil1 phosphorylation.

When combined with pil1(4D)-GFP, Δnce102 cells showed a similar, albeit slightly more severe phenotype than NCE102 pil1(4D)-GFP cells (Fig. S4c), indicating that phosphorylation at additional sites can enhance eisosome disassembly. Previous work identified at least seven additional phosphorylation sites in Pil1, which may mediate this effect (Zhang et al., 2004; Walther et al., 2007; Luo et al., 2008). Together, pil1(4A) epistasis on Δnce102 and enhancement of the pil1(4D) phenotype by Δnce102 suggest that Nce102 negatively regulates Pil1 phosphorylation.

Nce102 inhibits Pil1 phosphorylation

To substantiate these findings, we determined whether the phosphorylation state of Pil1 is altered in Δnce102 cells. To this end, we purified Pil1 fused to a tandem affinity purification (TAP) tag from wild-type and metabolically heavy lysine-labeled Δnce102 cells (stable isotope labeling by amino acids in cell culture [SILAC]; Fig. S2a; Ong et al., 2002) and analyzed it by two strategies. First, we mixed proteins of Pil1-TAP eluates 1:1 and separated them by SDS-PAGE, resulting in a clearly visible doublet of Pil1, where the upper band represents phosphorylated Pil1 (Walther et al., 2007). Separate analysis of the two bands by liquid chromatography (LC) mass spectrometry (MS)/MS revealed that contaminant proteins present in both bands have a 1:1 ratio of protein from wild-type and Δnce102 sample, as determined by comparing mean peptide peak intensities. In contrast, Pil1 from Δnce102 was 30% enriched in the upper phospho-Pil1 band (1.28 ratio, Pil1 heavy vs. light) and correspondingly decreased in the lower band (0.59 ratio, Pil1 heavy vs. light; Fig. 5a; and Fig. S2, c and d).

In a second approach, we directly mixed, digested, and analyzed Pil1 pull-down eluates by LC-MS/MS (Fig. S2a). From this approach, we identified many unphosphorylated peptides and, for example, the phosphorylated peptide harboring T233 of Pil1 from both wild-type and Δnce102 cells. Importantly, the phosphopeptide was more than threefold more abundant coming from the heavy lysine-labeled Δnce102 sample compared with the wild-type control (Fig. 5b; and Fig. S2, e and f). The total amount of Pil1 was equal in both experiments because unphosphorylated peptides were present in a 1:1 ratio (Fig. S2f). Together, these data demonstrate that Pil1 was present in a roughly equimolar ratio in both pull-down eluates but that phosphorylation at T233 was more than threefold increased in

Figure 5. Pil1 phosphorylation is increased in Δnce102 cells. [a] Pil1-TAP was purified from SILAC-labeled wild-type and Δnce102 cells, mixed in equal amounts, resolved by SDS-PAGE, and two resulting Pil1 bands were separately analyzed by MS. The contaminant Nsr1 was present in a 1:1 ratio from both strains in each band. Pil1 was 1.3-fold enriched in the upper band (red) and decreased to a ratio 0.6 in the lower band (black).

(b) Pil1-TAP purified from SILAC-labeled wild-type and Δnce102 cells was analyzed by MS. Unphosphorylated Pil1 peptide amino acids 222–248 is shown in black, and the T233 phosphopeptide is shown in red. (c) Pil1-TAP purified from SILAC-labeled untreated cells or treated with myriocin for 1 h was analyzed as in b. Representative data of three experiments are shown. Ratio H/L denotes the mean ratio of the abundance of heavy versus light-labeled peptides.
Nce102 is an inhibitor of Pil1 phosphorylation acting downstream of sphingoid bases. If this is the case, addition of exogenous sphingoid base would rescue the $\Delta$nce102 phenotype. Exogenously added sphingoid bases can enter the cell and rescue a sphingoid base synthesis defect because addition of 5 µM PHS suppressed the Pil1-GFP phenotype of the $lcb1\text{-}100$ mutant (which impairs sphingolipid synthesis) both at the permissive and restrictive temperatures (Fig. 7 a). In contrast, the eisosome defect of $\Delta$nce102 cells was not rescued by addition of PHS under conditions that rescued the $lcb1\text{-}100$ mutant phenotype (Fig. 7 a) or by a 10-fold higher concentration of PHS (unpublished data). Quantitation of eisosome number and cytосolic Pil1 levels confirmed the visual evaluation (Fig. 7 b).

These data show that Nce102 is not required for sphingoid base synthesis but rather acts downstream of it. Because PHS has no additive effect on $\Delta$nce102 cells, sphingolipids and Nce102 act in the same pathway (Fig. 7 b).

To further test this hypothesis, we investigated the interaction between myriocin treatment and $\Delta$nce102. If both act independent of each other, we expect an additive effect between them. However, this is not the case. As shown in images and quantitation of eisosomes, myriocin has no further effect on eisosomes in $\Delta$nce102 cells, confirming that sphingolipid signaling and Nce102 act in the same pathway on eisosomes (Fig. 7 c and d).

We previously showed that Pil1 phosphorylation occurs through the Pkh kinase pathway. First, we determined the epitatic relationship between Pkh kinase mutants and $\Delta$nce102 using a yeast strain that harbors a deletion of $PKH2$ and a temperature-sensitive allele of $PKH1$ ($pkh^{ts}$; Friant et al., 2001). Already at the permissive temperature, these mutations lead to a strong over-assembly effect on eisosomes. Specifically, $pkh^{ts}$ strains display large elongated threads of Pil1 at the plasma membrane with most of the membrane covered with Pil1 (Fig. 6; Walther et al., 2007). This phenotype is also very severe at the restrictive temperature, with most of the membrane covered with Pil1 (Fig. S4 e).

Combining $pkh^{ts}$ and the $\Delta$nce102 mutations, we found that double-mutant cells show a Pil1-GFP phenotype indistinguishable from the $pkh^{ts}$ phenotype at both 24°C and 37°C (Fig. S4 e). This indicates that Pkh kinases are required to obtain the $\Delta$nce102 phenotype and shows that Nce102 acts upstream of Pkh kinases, inhibiting them in a linear pathway.

Nce102 acts downstream of long chain bases in sphingoid base signaling

Our data suggest that Nce102 acts on Pil1 phosphorylation by inhibiting Pkh kinases. Because Pkh kinases are regulated by sphingoid bases and both, a block of sphingolipid synthesis and $\Delta$nce102, lead to increased Pil1 phosphorylation, Nce102 itself may be controlled by sphingolipids, acting upstream of the Pkh kinases. Alternatively, Nce102 could be required for efficient synthesis of sphingolipids that are then sensed by the kinases by some other route. One more possibility is that Nce102 acts independently of sphingolipids to regulate Pkh kinases.

To distinguish between these possibilities, we tested whether Nce102 is required for the synthesis of sphingoid bases. If this was the case, addition of exogenous sphingoid base would rescue the $\Delta$nce102 phenotype. Exogenously added sphingoid bases can enter the cell and rescue a sphingoid base synthesis defect because addition of 5 µM PHS suppressed the Pil1-GFP phenotype of the $lcb1\text{-}100$ mutant (which impairs sphingolipid synthesis) both at the permissive and restrictive temperatures (Fig. 7 a). In contrast, the eisosome defect of $\Delta$nce102 cells was not rescued by addition of PHS under conditions that rescued the $lcb1\text{-}100$ mutant phenotype (Fig. 7 a) or by a 10-fold higher concentration of PHS (unpublished data). Quantitation of eisosome number and cytосolic Pil1 levels confirmed the visual evaluation (Fig. 7 b).

These data show that Nce102 is not required for sphingoid base synthesis but rather acts downstream of it. Because PHS has no additive effect on $\Delta$nce102 cells, sphingolipids and Nce102 act in the same pathway (Fig. 7 b).

To further test this hypothesis, we investigated the interaction between myriocin treatment and $\Delta$nce102. If both act independent from each other, we expect an additive effect between them. However, this is not the case. As shown in images and quantitation of eisosomes, myriocin has no further effect on eisosomes in $\Delta$nce102 cells, confirming that sphingolipid signaling and Nce102 act in the same pathway on eisosomes (Fig. 7 c and d).

We previously showed that Pil1 hyperphosphorylation caused by decreased sphingolipid synthesis causes eisosome disassembly (Walther et al., 2007). If our hypothesis is true and Nce102 is an inhibitor of Pil1 phosphorylation acting downstream of Pil1 on Cdc55, these data suggest that the interaction between Pil1 and Nce102 is required for sphingolipid signaling.

Several studies show that Pil1 phosphorylation is mediated by Pkh kinases (Zhang et al., 2004; Walther et al., 2007; Luo et al., 2008). Therefore, we asked whether the effect of Nce102 on Pil1 phosphorylation occurs through the Pkh kinase pathway. First, we determined the epitatic relationship between Pkh kinase mutants and $\Delta$nce102 using a yeast strain that harbors a deletion of $PKH2$ and a temperature-sensitive allele of $PKH1$ ($pkh^{ts}$; Friant et al., 2001). Already at the permissive temperature, these mutations lead to a strong over-assembly effect on eisosomes. Specifically, $pkh^{ts}$ strains display large elongated threads of Pil1 at the plasma membrane with most of the membrane covered with Pil1 (Fig. 6; Walther et al., 2007). This phenotype is also very severe at the restrictive temperature, with most of the membrane covered with Pil1 (Fig. S4 e).

Combining $pkh^{ts}$ and the $\Delta$nce102 mutations, we found that double-mutant cells show a Pil1-GFP phenotype indistinguishable from the $pkh^{ts}$ phenotype at both 24°C and 37°C (Fig. S4 e). This indicates that Pkh kinases are required to obtain the $\Delta$nce102 phenotype and shows that Nce102 acts upstream of Pkh kinases, inhibiting them in a linear pathway.

$\Delta$nce102 cells. Therefore, the results of the two biochemical approaches converge, demonstrating that Pil1 phosphorylation is increased in $\Delta$nce102 cells.

Because Pil1 phosphorylation is inhibited by sphingoid bases (Zhang et al., 2004; Walther et al., 2007), we tested whether NCE102 deletion results in a similar effect on Pil1 phosphorylation as sphingolipid depletion. To this end, we measured the relative abundance of the Pil1 T233 phosphopeptide in cells where synthesis of sphingolipids was blocked for 1 h by myriocin, a drug targeting the serine palmitoyl transferase that catalyzes the rate-limiting step of sphingolipid synthesis, compared with wild-type cells. In this experiment, we detected a twofold increase of Pil1 phosphorylation at T233 after myriocin treatment compared with wild-type cells (Fig. 5 c and Fig. S2 g). This shows that the block of sphingolipid synthesis by myriocin and NCE102 deletion has a similar effect on Pil1 phosphorylation.

Nce102 acts on Pil1 via Pkh kinases

Several studies show that Pil1 phosphorylation is mediated by Pkh kinases (Zhang et al., 2004; Walther et al., 2007; Luo et al., 2008). Therefore, we asked whether the effect of Nce102 on Pil1 phosphorylation occurs through the Pkh kinase pathway. First, we determined the epitatic relationship between Pkh kinase mutants and $\Delta$nce102 using a yeast strain that harbors a deletion of $PKH2$ and a temperature-sensitive allele of $PKH1$ ($pkh^{ts}$; Friant et al., 2001). Already at the permissive temperature, these mutations lead to a strong over-assembly effect on eisosomes. Specifically, $pkh^{ts}$ strains display large elongated threads of Pil1 at the plasma membrane with most of the membrane covered with Pil1 (Fig. 6; Walther et al., 2007). This phenotype is also very severe at the restrictive temperature, with most of the membrane covered with Pil1 (Fig. S4 e).

Combining $pkh^{ts}$ and the $\Delta$nce102 mutations, we found that double-mutant cells show a Pil1-GFP phenotype indistinguishable from the $pkh^{ts}$ phenotype at both 24°C and 37°C (Fig. S4 e). This indicates that Pkh kinases are required to obtain the $\Delta$nce102 phenotype and shows that Nce102 acts upstream of Pkh kinases, inhibiting them in a linear pathway.
Figure 7. **Nce102 and sphingolipids act in the same pathway.** (a) *lcb1-100* but not *Δnce102* is suppressed by sphingoid bases. Wild-type (wt), *lcb1-100*, or *Δnce102* cells expressing Pil1-GFP were analyzed with or without addition of 5 µM PHS, and representative images are shown. (b) Eiosome number per mother cell (left) and cytosolic Pil1-GFP fluorescence (right) are shown. (c) Myriocin has no additive effect on *Δnce102* cells. Wild-type and *Δnce102* cells were treated for 1 h with 5 µM myriocin, and representative images are shown. (d) Quantitation of eiosome number per mother cell (left) and cytoplasmic Pil1-GFP fluorescence (right) of cells treated as in c. Error bars indicate SD. Bars, 5 µm.
of sphingolipids, we predict that overexpression of Nce102 will rescue eisosome disassembly when sphingolipid synthesis is decreased. To test this, we expressed Nce102-mars from the inducible Gal promoter in cells that have Pil1-GFP–marked eisosomes. When these cells are grown on raffinose, Nce102-mars is not expressed, and eisosomes appear normal, as these cells also express endogenous Nce102 (Fig. 8). When these cells grow on galactose, Nce102-mars is overexpressed (Fig. 8). Strikingly, when we blocked sphingolipid synthesis in these cells by treating them with myriocin, the normal effect of disassembling eisosomes apparent in control cells was completely blocked (Fig. 8). This shows that increasing Nce102 levels blocks the effect of inhibiting sphingolipid synthesis on eisosomes.

Together, our genetic experiments thus place Nce102 in a linear pathway inhibiting Pkh kinases and suggest a relationship: sphingoid bases → Nce102–| Pkh1/2 → Pil1 phosphorylation → eisosome disassembly. In this scenario, Nce102 would function as part of a sensor relay for sphingoid base or sphingolipid levels.

Nce102 localization responds to changes in sphingolipid levels

Because Nce102 negatively regulates Pkh kinases that localize to eisosomes, we next tested whether Nce102 distribution between MCCs at eisosomes and the rest of the plasma membrane is affected by sphingolipid levels. To this end, we determined Nce102-GFP localization after blocking sphingolipid synthesis. Strikingly, after a 1 h incubation of cells with myriocin, the punctate pattern of Nce102-GFP localization in MCCs disappeared, and the protein distributed diffusely across the plasma membrane (Fig. 9 a). Consistently, in intensity plots of surface images, myriocin-treated cells show a rather flat distribution of the Nce102-GFP signal, whereas control samples show many Nce102-GFP peaks corresponding to MCCs at eisosomes (Fig. 9 b). Relocalization of Nce102-GFP could be reversed by addition of exogenous PHS for a short time (15 min). In this case, the MCC pattern of Nce102-GFP localization reappeared, showing an even more pronounced pattern of Nce102-GFP foci than normal (Fig. 9 b).

Nce102 relocalization could be caused by redistribution of existing protein in the plasma membrane or new protein synthesis under conditions in which myriocin blocks the efficient incorporation of Nce102 in MCCs. To distinguish these possibilities, we added myriocin after a preincubation with the translation-blocking drug cycloheximide. During persistent translation block, Nce102 localized normally to MCCs and the remainder of the membrane (Fig. 9 c). Moreover, it still relocalized from MCCs after myriocin treatment, indicating that this phenomenon is not dependent on protein synthesis (Fig. 9 c). Similarly, when PHS was added to cells in which translation was blocked, Nce102 relocalization occurred normally (Fig. 9 c).

To test whether this effect is specific to the availability of sphingoid bases or a more general response to sphingolipid levels, we added aureobasidin to cells for 1 h. This drug inhibits complex sphingolipid synthesis from ceramide downstream of the formation of sphingoid bases (Nagiec et al., 1997). We observed the same Nce102-GFP redistribution in the plasma membrane after aureobasidin or myriocin addition (Fig. 9 a and b). Consistent with the downstream block of sphingolipid synthesis by aureobasidin, addition of exogenous sphingoid bases did not result in reformation of the punctate Nce102 pattern (Fig. S4).

Together, these data suggest an equilibrium of two pools of Nce102-GFP localizing to MCCs at eisosomes or to spaces in between that is shifted by levels of sphingolipids. Consistent with this notion, addition of PHS to untreated cells shifted more Nce102-GFP into punctate structures, rendering them more pronounced (Fig. 9 a and b).

In the yeast plasma membrane, many proteins are sensitive to extraction by detergents to a different level, and Nce102 was previously described operationally as an abundant component of detergent-resistant membranes (Bagnat et al., 2000). To test whether Nce102 distribution between MCCs and the remainder...
proteins embedded in mostly phospholipid bilayers. This difference can be tested in a velocity sedimentation gradient. Nce102 from untreated cells was present in most fractions of the gradient, indicating that it is localized both to detergent-resistant and other membranes (Fig. 9 d). When treated with myriocin, Nce102 of the plasma membrane observed by microscopy is reflected in its partitioning between different membrane environments, we analyzed its solubility in a buffer containing 1% Triton X-100 at 4°C. Proteins partitioning into sphingolipid/ergosterol-rich domains show lower solubility in this buffer compared with proteins embedded in mostly phospholipid bilayers. This difference can be tested in a velocity sedimentation gradient. Nce102 from untreated cells was present in most fractions of the gradient, indicating that it is localized both to detergent-resistant and other membranes (Fig. 9 d). When treated with myriocin, Nce102
partitioning changed toward the bottom of the gradient, indicating higher solubility. After short treatment of these cells with PHS, Nce102 redistributed to more detergent-insoluble membrane fractions at the top of the gradient. Pma1, a marker for MCP membranes, did not significantly alter its migration in the gradient after either myriocin or PHS treatment.

Together, these results show that relative levels of Nce102 in different plasma membrane domains are regulated by sphingolipids and that this redistribution is highly sensitive to changes in membrane composition because it can be observed after small perturbations that do not change Pma1 behavior. These data are consistent with the hypothesis that Nce102 sphingolipid-mediated redistribution is the mechanism by which Nce102 regulates Pil1 phosphorylation. In this model, Nce102 is recruited to MCCs at eisosomes under conditions of sufficient sphingolipids to repress Phk kinase activity toward Pil1 and released from there when sphingolipid levels drop, for example, after inhibition of their synthesis by myriocin or aureobasidin. To test this, we determined the localization of Nce102-mars relative to Phk kinases. Phk2-GFP localizes in very dim spots that colocalize with eisosomes and Nce102 foci (Fig. S5, a and b). Importantly, when we blocked sphingolipid synthesis with myriocin, Nce102-mars relocated from these foci, leaving Phk2-GFP behind (Fig. 5, c and d).

If Nce102 acts as a plasma membrane sphingolipid sensor, then its partitioning should be upstream and independent of the assembly state of eisosomes. Alternatively, Nce102 redistribution could be a consequence of eisosome disassembly after inhibition of sphingolipid synthesis. To test this directly, we used pil1(4A) mutant cells in which Pil1 cannot be sufficiently phosphorylated. Eisosomes are therefore resistant to activation of Phk kinases (Walther et al., 2007). As expected, when cells that express pil1(4A)-GFP as their sole copy of Pil1 are incubated with myriocin, eisosomes remain stable because Pil1(4A) does not get sufficiently phosphorylated to disassemble (Fig. 9 e).

To determine whether Nce102-GFP redistribution is caused by disassembly of eisosomes, we investigated the localization of Nce102-GFP in pil1(4A) cells. We found it to distribute normally in both MCCs and the remainder of the plasma membrane (Fig. 9 f). When we added myriocin to these cells, eisosomes remained assembled as a result of the pil1(4A) mutation, yet Nce102-GFP relocated to become diffusely distributed throughout the plasma membrane (Fig. 9 f). To test whether this is a general property of MCC proteins, we performed similar experiments with cells expressing Sur7-mars. When we treated these cells with myriocin, the intensity of Sur7 signal in MCC decreased as Pil1 disassembled (Fig. 9 g; not depicted), but this could be completely blocked by expressing Pil1(4A) (Fig. 9 h). Thus, Nce102-GFP has a distinct behavior from other MCC components and redistributes in the plasma membrane dependent on sphingolipids but independently of the eisosome assembly state.

Discussion

We report a comprehensive screen for genes involved in Pil1-GFP localization. Recently, a similar screen using an MCC reporter identified 27 genes (Grossmann et al., 2008). Compared with that screen, we found roughly three times more genes affecting Pil1 localization (n = 88). It remains to be seen whether this difference is caused by different thresholding during the screen or biological differences between MCCs versus eisosomes. Because Pil1 and MCC components colocalize and Pil1 is required for normal MCC formation, it is surprising that there is little overlap between the two screens: only NCE102, SUR4, MNN10, and few biological processes were found in both. Examples include retrograde transport from the Golgi apparatus to the ER (VPS52 and VPS54 in the MCC screen; VPS51 and VPS53 in the Pil1 screen). Therefore, these genes and processes likely have a global effect on plasma membrane organization affecting MCCs and eisosomes. Genes that were identified only in one screen likely perform more specific functions; future experiments will, for example, show whether YMR086W, YMR031C, or genes encoding the NatC complex are important for eisosomes but not MCCs.

Besides genes globally affecting the plasma membrane, we expected to find genes impacting eisosome organization directly as well as genes that alter sphingolipid signaling, resulting in altered Pil1 phosphorylation and assembly. In the later class, we identified Nce102. Besides it, also SUR4, ISC1, and SAC1 are likely to act on eisosomes through sphingolipid signaling. Deletion of SUR4, required for fatty acid elongation during sphingolipid synthesis (Han et al., 2002; Paul et al., 2006), or deletion of ISC1, the homologue of mammalian neutral sphingomyelinase (Sawai et al., 2000), results in accumulation of complex sphingolipids. In our screen, both Δisc1 and Δsur4 cells showed hyper-assembled Pil1-GFP, which is the opposite effect of depleting complex sphingolipids by inhibiting their synthesis (Table S2). In addition, it was recently reported that Δsac1 cells have elevated sphingoid bases and reduced levels of complex sphingolipids (Brice et al., 2009), and we found them to have fewer eisosomes and increased cytoplasmic Pil1-GFP signal (Table S2). We expect that other genes identified will also turn out to play a role in sphingolipid biology.

In this study, we focused on the function of Nce102, a multi-spanning plasma membrane protein required for normal eisosomes, MCC formation, and plasma membrane organization. Initially, Nce102 was identified by Cleves et al. (1996) as required for nonclassical export of mammalian galexin from yeast. The mechanism of Nce102 function in this pathway was not investigated. Because the assay used requires solubilization of cell-associated galexin using high pH, it is possible that the basis of the effect could be altered protein extractability from Δnce102 cells because of their altered plasma membrane.

Our experiments revealed that Nce102 has fascinating properties, suggesting that it might act as part of a sphingolipid sensor. Most remarkable, its localization is dynamic and responsive to changes in sphingolipid levels: Nce102 partitions between two domains in the plasma membrane, MCCs overlying eisosomes and the rest of the plasma membrane. We show that the distribution between these two domains is controlled by sphingolipid availability. Nce102 localization to MCCs brings it into close contact with the underlying eisosomes and Phk kinases (Fig. S5; Walther et al., 2007). Nce102 negatively regulates the activity of these kinases, and, in the presence of sphingolipids, blocks their downstream functions. Conversely, if sphingolipid...
synthesis is blocked, Nce102 redistributes away from Pkh kinases (Fig. S5), alleviating their inhibition. Therefore, we propose a model that Nce102 acts as part of a sphingolipid-sensing mechanism and that its distribution in the plasma membrane regulates Pkh kinases (Fig. 10). In the simplest hypothesis, Nce102 could simply accomplish repression of the kinases by regulated juxtaposition to them, which is a common scheme in kinase signaling. Based on filipin staining, MCCs were suggested as sites of increased ergosterol concentration in the plasma membrane (Grossmann et al., 2007), and because sterols preferentially interact with sphingolipids, it is likely that sphingolipids are also concentrated there, forming detergent-resistant, liquid-ordered membrane domains or lipid rafts (Simons and Ikonen, 1997; Malinska et al., 2003) where Nce102 was found previously (Bagnat et al., 2000). Thus, it is possible that Nce102 also reacts to ergosterol levels in the plasma membrane. However, we did not observe an effect of nonessential erg mutants or block of sterol synthesis on eisosomes or Nce102 localization (unpublished data). Consistent with our model, Nce102 localizes to eisosome remnants that also show increased filipin staining, likely reflecting increased concentration of ergosterol and possibly sphingolipids (Grossmann et al., 2007). Alternatively, filipin might preferentially report on free sterols not in complex with sphingolipids, and staining of MCCs could actually indicate a lower concentration of sphingolipids in this compartment. This view is supported by a recent observation that filipin staining increases if sphingolipid synthesis is blocked (Jin et al., 2008). A further alternative is that Nce102 could directly bind sphingolipids, changing its affinities to other proteins that help localize it to MCCs and/or switching its activity as a Pkh kinase inhibitor on and off. In either model, Nce102 leaves the MCC when sphingolipid levels are low, releasing its inhibition of Pkh kinases that now phosphorylate P11 and other targets. This is consistent with our observation that Nce102 detergent solubility changes after inhibition of sphingoid base synthesis, indicating that it partitions between different membrane environments. Most likely, this change corresponds to the relocation of Nce102 from MCCs to the remainder of the membrane observed by microscopy. The interpretation of this result, however, remains vague, as most proteins in the yeast plasma membrane differ only in the degree of their resistance to Triton X-100 detergent extraction. For example, the MCP marker Pma1 was also previously used as a marker for detergent-resistant lipid rafts (Bagnat et al., 2000; Lee et al., 2002; Malinska et al., 2003). The difference in Triton X-100 solubility between Nce102 and Pma1 after myriocin treatment might therefore indicate that these proteins differently partition into such lipid rafts or that the MCP is actually more complex and contains subdomains not easily resolved by light microscopy. Consistent with the later notion, TORC2 (Tor kinase complex 2) is localized at a distinct plasma membrane domain separate from MCC and MCP and is also partially detergent resistant (Aranova et al., 2007; Berchtold and Walther, 2009).

The sensing mechanism of sphingolipids in the plasma membrane by Nce102 suggested in this study is different from a previous model positing that soluble sphingoid bases in the cytoplasm directly control Pkh kinases (Zhang et al., 2004; Liu et al., 2005). It is possible that sphingolipids control the activity of Pkh kinases at many levels. Sphingoid bases could, for example, directly regulate Pkh kinases as in vitro experiments suggest (Zhang et al., 2004), and complex sphingolipids could affect signaling via Nce102. However, the in vivo effect of direct inhibition of Pkh kinase activity toward P11 by sphingoid bases is probably minor compared with the Nce102 pathway, as exogenously added PHS was not able to counteract the ∆nce102 hyperphosphorylation effect on eisosomes.

Our model of regulation of Pkh kinases by complex sphingolipids via the transmembrane protein Nce102 would also bridge the topological barrier between the cytoplasmic Pkh kinases and complex sphingolipids mainly concentrated in the outer leaflet of the plasma membrane (van Meer et al., 2008).

Downstream of sphingolipid sensing, the Nce102–Pkh pathway regulates phosphorylation of P11 that, when increased, always correlated with eisosome disassembly, e.g., in ∆nce102 cells. This effect could be blocked by mutating phosphorylated P11 residues to alanines that we previously found were required and sufficient for the effect of Pkh kinases on eisosomes (Walther et al., 2007). This is different from findings by Luo et al. (2008), who reported that a mutant form of P11 harboring five phosphosites mutated to alanine (S6A, S59A, T233A, S273A, and S299A) cannot assemble properly and argued that phosphorylation of P11...
is important for assembly of eisosomes rather than disassembly. In this study, even a mutant that lacks these five sites and even two additional sites (S6A, S45A, S59A, S230A, T233A, S273A, and S299A) still assembles into eisosomes correctly (unpublished data). The reason for this difference is unclear but might indicate that additional pathways to the Nce102–Pkh kinase module regulate Pkh phosphorylation in a complex fashion.

Besides phosphorylation of Pil1, Pkh kinases modify many plasma membrane functions. Therefore, as expected, ∆nce102 cells show altered organization of the plasma membrane, as observed for MCCs, MCPs, and the endocytic foci marked by the lipophilic dye FM4-64. Recently, it was also shown that ∆nce102 cells have accelerated endocytosis rates of some membrane transporters (Grossmann et al., 2008). Pkh kinases also participate in processes as diverse as cortical actin patch organization, cell integrity signaling, endocytosis, and eisosome organization (Inagaki et al., 1999; Sun et al., 2000; deHart et al., 2002; Roelants et al., 2002; Zhang et al., 2004; Liu et al., 2005; Grosshans et al., 2006; Walther et al., 2007; Luo et al., 2008). Regulation of these diverse processes may help control the composition of the plasma membrane according to need, perhaps constituting part of a negative feedback loop that targets genes involved in sphingolipid synthesis. Indeed, expression of such genes, e.g., LCB2, FEN1, and SUR4, is strongly negatively correlated to the expression of NCE102 when the latter is regulated in response to various physiological conditions, e.g., during diauxic shift, nitrogen depletion, or heat shock (correlations for NCE102/SUR4 are: diauxic shift, −0.94; nitrogen starvation, −0.66; and heat shock, −0.85; Fig. S3, b–d; DeRisi et al., 1997; Gasch et al., 2000). In addition, after prolonged incubation with PHS, we observed Nce102-GFP signal at the vacuole (unpublished data), perhaps reflecting an adaptation to recalibrate the set level of Pkh signaling after long times with high sphingolipids levels.

An important role of Nce102 in regulation of sphingolipids is also supported by the ability of its deletion to suppress the growth defect of a mutation in the serine palmitoyl transferase subunit TSC3 (Schuldiner et al., 2005; unpublished data) or the growth inhibition caused by myriocin (Fig. S3 a), both of which reduce the first and rate-limiting step in sphingolipid synthesis.

Salient features of the sphingolipid–Nce102–Pkh kinase signaling network are likely conserved between yeast and other eukaryotes. Nce102 shares homology with the synaptoerymin/cellugyrin protein family (Belfort et al., 2005), but the molecular roles of these proteins are not understood. In contrast, mammalian PDK1 kinases (the homologues of yeast Pkh kinases) are well characterized, and the general architecture of downstream signaling is conserved (Casamayor et al., 1999). In either system, full activation of AGC kinases, such as AKT, Sch9, serum glucocorticoid kinase, or Ypk1/2, requires phosphorylation both by PDK1 (in mammalian cells) or Pkh kinases (in yeast) and in addition by the conserved kinase complex TORC2 (Powers, 2007). For yeast, TORC2 signaling has been implicated in the regulation of sphingolipid biosynthesis (Beeler et al., 1998; Tabuchi et al., 2006; Aronova et al., 2008). This effect of TORC2 is mediated by the Pkh kinase target Ypk2 (Aronova et al., 2008). Additionally, the Slm proteins were identified as targets of both the TORC2 and Pkh kinase signaling pathways and to regulate a late step in the synthesis of complex sphingolipids (Tabuchi et al., 2006). It is therefore likely that the TORC2 and Pkh1/2 pathways collaborate to regulate sphingolipid metabolism in yeast. Given the similarity of the signaling pathway components and its architecture in higher eukaryotes, their output may also be evolutionarily conserved.

Materials and methods

Visual screen
To generate a library of deletion mutants each expressing Pil1-GFP, we performed a modification of the synthetic genetic array screen as described previously (Longo et al., 2001). In short, a MAFA strain containing a chromosomal copy of Pil1-GFP marked with a NAT marker, the CAT1 gene disrupted by a construct that encodes the MAFA promoter driving expression of the HIS3 gene and the YLP1 gene disrupted by a construct expressing LEU2 from the MFα promoter (KEM108), was crossed to the MAFA deletion library BY4741 (each strain marked with KAN). Diploids were selected on G418 and nourseothricin and sporulated. From the sporulation, MAFA haploids containing both Pil1-GFP and the deletion gene were selected with successive pinning on –HIS (selection for MAFA cells), G418 (selection for the diploid colonies), kan (selection for haploid cells harboring can1Δ), s-(2-aminoethyl)-cysteine hydrochloride (selection for haploid cells harboring ylp1Δ), and nourseothricin (selection for Pil1-GFP-containing media).

For imaging, cells were grown overnight to saturation in 384-well plates, transferred to 96-well plates, diluted, and grown for 9 h until they reached mid-log phase. Cells were transferred to glass-bottom 96-well plates coated with concanavalin A and imaged with a 40× high NA objective in an ImageXPress Micro (MDS Analytical Technologies). At least six different images were taken for each deletion strain.

The images were visually inspected using the software by the microscope manufacturer and classified using three categories: increased cytoplasmic Pil1-GFP fluorescence, altered number or eisosomes, and altered pattern of eisosomes. Strains that showed a phenotype in this first round of screening were regrown and imaged by using a confocal microscope (LSM510; Carl Zeiss, Inc.).

Two optical mid-section and two top-section images were taken for each strain, showing 15–40 cells per image. Images were visually analyzed, and several parameters of the Pil1-GFP signal on the surface of cells were quantitated using an image interpretation script developed in MATLAB that we named EISURAN (both the source code and an executable MATLAB file can be found at http://www.biochem.mpq.de/en/rq/walther/news/index.html). In short, EISURAN first subtracts background from the images and then finds the edge of a cell by image dilation. To facilitate the quantitation of signal from assembled Pil1, the script thresholds the image using Otu’s method (Otus, 1979). From the resulting binary image, EISURAN calculates the number of positive pixels per cell, a measure for the area covered by eisosomes (percentage of cell surface covered by eisosomes). It then calculates the mean size of the connected clusters (mean pixel number per eisosome cluster on cell surface). To eliminate small background clusters, a minimum of 20 pixels are used for the lower cut off. In some conditions, very large values result caused by connection of eisosomes into very large clusters, which are sometimes string formed. To determine how much Pil1 is in individual eisosomes, EISURAN determines the mean intensity of each cluster by applying the binary image as a mask on the original image, integrating the intensity in each cluster, and averaging this intensity over all clusters in an image (mean integrated intensity per eisosome cluster on cell surface). Quantitation of eisosome number was based on the mean number of eisosomes counted by two independent observers in optical mid sections of mother cells (eisosome number; mean for the wild type = 11.5 ± 1.55).

The cytoplasmic signal was quantitated as the mean intensity of a 50 × 50-pixel area in the cytoplasm (cytoplasmic Pil1-GFP signal) visible in a confocal mid section of the cell using Images (National Institutes of Health). The resulting values were averaged from at least 20 cells, analyzed by hierarchical clustering, and displayed using R software (http://www.r-project.org).

Yeast strains and plasmids
All yeast strains used as well as their genotypes are listed in Table S1. The starter strain used for the screen Pil1-GFP::NAT (KEM108) was generated in the strain YMS196 (provided by N. Krogan, University of California)
were grown in the presence of 20 mg/l normal Cycloheximide (Sigma-Aldrich) was added in a concentration of 100 µg/ml were added in concentrations as indicated and incubated for 1 h or 15 min.

The resulting peptides were extracted with 30% acetonitrile and 3% trifluoroacetic acid, reduced in a speed vacuum centrifuge, and desalted and concentrated on a reversed-phase column (C18 StageTips; RapsilBep, 2005). In a different approach, the mixed eluates were precipitated with chloroform/methanol and resuspended in 8 M urea. Proteins were alkylated, reduced, and directly digested in solution overnight at RT with LysC. Peptides were desalted and concentrated on StageTips. Peptides were eluted from the StageTips by passage of 2x 20 µl volume of B (20 µl volume of B (80% acetonitrile and 0.5% acetic acid). The volume was reduced to 4 µl in a speed vacuum centrifuge, and 2 µl of 1% trifluoroacetic acid was added to acidify the sample. Peptides were separated on line to the mass spectrometer by using an HPLC system (1200; Agilent Technologies). 5-µl samples were loaded with constant flow of 500 nl/min onto a 1.5-cm fused silica emitter with an inner diameter of 75 µm (Proxeon Biosystems) packed in house with reverse-phase 3-µm resin (ReproSilPur C18-AQ; provided by Dr. Maisch GmbH). Peptides were eluted with a segmented gradient of 10–60% solvent B over 110 min with a constant flow of 250 nl/min. The HPLC system was connected to a linear trap quadrupole Orbitrap, Thermo Fisher Scientific) via a nanoscale LC interface (Proxeon Biosystems). The spray voltage was set to 2.2 kV, and the temperature of the heated capillary was set to 180°C.

\[\text{The mass spectrum was acquired in negative ion mode. Survey full scan MS spectra (m/z = 300–1,600) were acquired with a resolution of 60,000 at m/z = 400 after accumulation of 1,000,000 ions. Isolation of detergent-resistant membranes

Detergent-resistant membranes were isolated essentially as described previously (Bagnat et al., 2000). In brief, 20 ODs Nce102-TAP–expressing yeast cells were harvested by centrifugation. The pellets were washed once with water and lysed in TNE buffer (50 mM Tris-HCl, pH 7.4, 150 mM NaCl, and 5 mM EDTA) by vortexing with glass beads twice for 5 min each at 4°C. The lysate was cleared of unbroken cells by centrifugation at 5000 rpm for 5 min and incubated with Triton X-100 (1% final) for 30 min on ice. 250 µl lysate was adjusted to 40% Optiprep by adding 500 µl of 60% Optiprep solution and overlaid with 1.2 ml of 30% Optiprep in TXNE (TNE and 0.1% Triton X-100) and 200 µl TXNE. The samples were centrifuged at 55,000 rpm for 2 h in a rotor (S55, Sorvall), and five fractions of equal volume were collected from the top. Proteins of each fraction were precipi-

tated with 20% trichloroacetic acid on ice for 15 min on ice. Aqueous phases were re-

suspended in 50 µl 2x sample buffer (0.24 M Tris, pH 8.0, 8% SDS, 1 mM DTT, 40% glycerol, and 0.4% bromphenol blue) and heated at 65°C. 25 µl aliquots were loaded onto 12% SDS-PAGE gel and analyzed by Western blotting. Nce102-TAP was detected with a rabbit polyclonal antibody (Sigma-Aldrich), Pma1 with a rabbit anti-Pma1 antibody (Santa Cruz Biotechnology, Inc.), and a horseradish peroxidase–coupled goat anti–rabbit IgG antibody (Santa Cruz Biotechnology, Inc.).

Fig. S1 shows a flowchart of the screening process and the quantitation of Pil1-GFP mutant phenotypes. Fig. S2 shows mass spectrometric analysis of Pil1 phosphorylation in wild-type and Nce102 mutants. Fig. S3 shows growth curves of Pil1-deletion library, Ron Vale for use of his high throughput microscope, and Nico Shummar for his invaluable expertise to image the Pil1-GFP deletion library. We also thank Stefan Jentsch, Robert Farese Jr., Lena Karotki, Natalie Krahmer, and Doris Bercholdt for discussions, Howard Riezman [University of Geneva, Geneva, Switzerland] for providing reagents, and Andrew Kuchinsky for sharing unpublished data. This work was supported by the Max Planck Society, the German Research Association (DFG; grant WA 1669/2-1), the German-Israeli Foundation (grant G-2193-1838.9), and the Human Frontiers Science Program [to T.C. Walther]. K. Maseira is a recipient of an aging training grant from National Institutes of Health/National Institute on Aging. P. Walter is a Howard Hughes Medical Institute Investigator. P.S. Aguilar is supported by the ANII (grant G-2193-1838.9), and the Human Frontiers Science Program (to T.C. Walther). F. Z. Idrissi, J. Lechner, H. Riezman, and M.I. Geli. 2006.
