ABSTRACT

We address the question of whether or not assembly bias arises in the absence of highly non-linear effects such as tidal stripping of haloes near larger mass concentrations. Therefore, we use a simplified dynamical scheme where these effects are not modelled. We choose the punctuated Zel’dovich (PZ) approximation, which prevents orbit mixing by coalescing particles coming within a critical distance of each other. A numerical implementation of this approximation is fast, allowing us to run a large number of simulations to study assembly bias. We measure an assembly bias from 60 PZ simulations, each with 512³ cold particles in a 128 h⁻¹ Mpc cubic box. The assembly bias estimated from the correlation functions at separations of \( \lesssim 5 h^{-1} \) Mpc for objects (haloes) at \( z = 0 \) is comparable to that obtained in full N-body simulations. For masses \( 4 \times 10^{11} h^{-1} M_\odot \), the ‘oldest’ 10 per cent haloes are three to five times more correlated than the ‘youngest’ 10 per cent. The bias weakens with increasing mass, also in agreement with full N-body simulations. We find that halo ages are correlated with the dimensionality of the surrounding linear structures as measured by the parameter \( (\lambda_1 + \lambda_2 + \lambda_3)/(\lambda_0^2 + \lambda_2^2 + \lambda_3^2)^{1/2} \) where \( \lambda_i \) is proportional to the eigenvalues of the velocity deformation tensor. Our results suggest that assembly bias may already be encoded in the early stages of the evolution.

Key words: methods: N-body simulations – methods: numerical – galaxies: clusters: general – galaxies: haloes – dark matter.

1 INTRODUCTION

A fundamental question in cosmology is the relation between the galaxy distribution and the underlying density field of the gravitationally dominant dark matter. According to the standard paradigm of structure formation, galaxies are harboured in stable virialized objects (haloes) made of dark matter particles. An assumption that has been often made is that the clustering properties of haloes depend on their mass alone. Although the assumption seems over-simplistic given the complexity of the hierarchical process of halo formation, it is sustained by the excursion set theory (Bond et al. 1991; Lacey & Cole 1993; Mo & White 1996) and by results of N-simulations of intermediate resolution (Lemson & Kauffmann 1999; Percival et al. 2003). Only recently Gao, Springel & White (2005) used a simulation of exceptionally large dynamical range (the Millennium Simulation, Springel et al. 2005) to show that the clustering of haloes depends also on the their age, which is defined as the time since a halo acquired half of its current mass. They have found that the ‘oldest’ 10 per cent of the haloes with mass \( 10^{11} h^{-1} M_\odot \) are more than 5 times more correlated than the ‘youngest’ 10 per cent haloes of the same mass. This assembly bias has been confirmed by Harker et al. (2006) using marked correlation functions on the same simulation, and by Wechsler et al. (2006) and Jing, Suto & Mo (2007) using independent simulations. Wetzel et al. (2007) also found dependence of clustering on halo history, but only when using a different definition for the assembly redshift.

We still lack a completely satisfactory explanation for the origin of assembly bias. For Gaussian initial conditions, simple arguments based on the spherical collapse model applied to narrow and broad initial density peaks which would collapse to haloes of the same mass at the present time do predict an assembly bias, but with younger haloes being more clustered than older ones. This trend of the bias is opposite to what is seen in simulations. Tidal stripping has been also invoked as a possible mechanism (e.g. Diemand, Kuhlen & Madau 2007). Because of mass stripping by the tidal gravitational field of the large mass concentration, nearby haloes would have been of higher mass in a different environment. Therefore, these haloes would have earlier formation times and would be more biased than haloes of the same mass in the field. Avila-Reese et al. (2005) suggested tidal stripping as a mechanism responsible for generation of assembly bias in the high-density regions, whereas in low-density regions the cosmological initial conditions play a more important role. Maulbetsch et al. (2007), Wang, Mo & Jing (2007) and Desjacques (2007) suggest that the halo mass-accretion is less efficient in denser regions due to large-scale tidal fields. However, the extent of this effect is difficult to assess. Here, we examine whether the bias can, at least partially, arise in the quasi-linear evolution (i.e. over scales where the flow is still laminar). In order to eliminate highly non-linear effects such as tidal stripping, we adopt...
approximate methods based on the Zel’’dovich approximation (Zel’dovich 1970) where particles move on straight lines independent of the motion of other particles. The Zel’dovich approximation is an analytic solution to planar cosmological perturbations up to the stage where multistreaming appears. For three-dimensional perturbations, the approximation is a reasonable description of quasi-linear dynamics away from multistreaming regions (e.g. Nusser et al. 1991). In order to extend the applicability of this approximation beyond multistreaming, we adopt the following scheme. Particles initially move in straight lines according to Zel’dovich, but they are merged together when they come within a critical distance of each other. This merging (sticking) produces an object with mass and linear momentum equal the total of its components. The critical distance is taken to depend on time like a diffusion length, as inspired by the adhesion approximation. This is known as the punctuated Zel’dovich (PZ) approximation (Fontana et al. 1995). This approximation is ideal for our purposes as it does not incorporate highly non-linear effects and also it is fast and easy to implement. Further, it readily provides merging trees for individual objects.

The outline of the paper is as follows. In Section 2, we discuss the Zel’dovich approximation and our implementation of the PZ scheme to describe the evolution in the quasi-linear regime. In Section 3, we present the PZ simulations and compare them with results from full dynamics. Our main results for halo biasing in the PZ simulations are presented in Section 4. We conclude with a general discussion in Section 5.

2 THE APPROXIMATE DYNAMICS

According to the Zel’dovich approximation, the time-dependent position, $x$, of a particle with initial (Lagrangian) coordinate $q$ is

$$x = q + D(t)\theta(q),$$

(1)

where we work with comoving coordinates, the function $D(t)$ is the gravitational growth rate of linear density fluctuations and $\theta(q)$ is a vector field which is a function of $q$ only and is assumed to be derived from a potential. The physical peculiar velocity is

$$v = a(t)dx/dt = aD\theta,$$

where $a(t)$ is the expansion factor of the cosmological background. The relation (1) yields a reasonable description of the gravitational evolution in the quasi-linear regime (e.g. Weinberg & Gunn 1990; Nusser et al. 1991), but fails near collapsed regions where multistreaming occurs. The PZ approximation is an extension of (1), which prevents the coating away of particles in collapsed regions and yet preserves the simplicity of the Zel’dovich kinematics. In the PZ, one starts with equal mass particles located at a uniform cubic grid at some initial time $t_i \to 0$. A particle is displaced from an initial position, $q$, at $t_i$ according to (1) until it comes within a distance of $d_i$ of another particle. The two particles are then merged together to form an ‘object’ having their total mass and linear momentum, and placed at their centre of mass. The newly formed object is then moved according to the Zel’dovich relation (1) with $\theta$ determined from momentum conservation. The scheme is applied to describe the further merging and evolution of objects (and particles).

We interpret the PZ in the framework of the adhesion approximation according to which (e.g. Nusser & Dekel 1990; Shandarin 1991)

$$\frac{d\theta}{dD} = v\Delta \theta,$$

(2)

The viscous term modifies the Zel’dovich ansatz $\theta = \text{constant}$ in regions with high-velocity gradients and prevents orbit crossing. Viscosity affects the flow over (comoving) scales $\lesssim \sqrt{D\nu}$. Above these scales, the flow is described by the usual Zel’dovich approximation. For $d_i \propto \sqrt{D\theta}$, the PZ is reminiscent of the adhesion approximation except that it ignores the details of the flow on scale $\lesssim \sqrt{D}$ by coalescing objects which are within a distance $d_i$ of each other. Here, we work with $d_i = \sqrt{D}$, as motivated by the adhesion approximation.

3 THE SIMULATIONS

We have run 60 PZ simulations, each with $512^3$ equal mass particles in a $128 h^{-1}$ Mpc cubic box on the side. The initial conditions correspond to a random Gaussian realization of the cold dark matter (CDM) scenario in a flat universe without a cosmological constant. The dependence on the background density parameters comes through the initial power spectrum but the dynamics is nearly independent of these parameters when the linear growth factor is used as the time variable (Nusser & Colberg 1998). Therefore, apart from the effect of the initial power spectrum, the final result should be independent of the cosmological background. Thus, the particle mass is $4.3 \times 10^9 h^{-1} M_{\odot}$. The dimensionless value of the Hubble constant is $h = 0.73$ and the rms value of the initial mass fluctuation in a sphere of $8 h^{-1}$ Mpc, as extrapolated to current time, is $\sigma_8 = 0.8$. The particles are moved forward in time from $z = 1000$ to 0 according to the PZ approximation with $d_i = \sqrt{D\nu}$ with $v = 1 h^{-2}$ Mpc$^2$ which sets a spatial resolution of $1 h^{-1}$ Mpc at the present time ($D = 1$). To further improve performance of the PZ, we smooth the initial velocity and density fields with a Gaussian window of width equal to $\sigma = 1 h^{-1}$ Mpc.

Our time variable is the growth factor $D$ and the time-step, $dD$, is such that $|\theta_{\text{max}}| dD = 0.1 d_i$, where $\theta_{\text{max}}$ is the speed of the fastest object.

For purposes of history tracking, each object is assigned a unique ID. When objects merge, the newly formed objects inherit the ID of the most massive progenitor. Object histories are tabulated in time slices separated by $\delta D = 1/100$.

At the final time, the average number of objects per simulation is $7 \times 10^4$ with $10^7$ being more massive than $4.3 \times 10^{11} h^{-1} M_{\odot}$ which is the minimal halo mass we consider for the study of assembly bias. The number of haloes in all 60 simulations is comparable to that in the millennium simulation.

The PZ approximation is neither expected nor intended to model highly non-linear dynamics. Indeed, it is because it misses highly non-linear effects that we use it in this study. However, it is prudent to make a general comparison of our implementation of the PZ scheme with results from full dynamics. To make a direct comparison, we have run the PZ scheme and a Particle–Mesh (PM) (Bertschinger & Gelb 1991) $N$-body code on the same initial conditions for $256^3$ particles in cubic box of $64 h^{-1}$ Mpc on the side. The initial conditions correspond to a flat CDM universe without a cosmological constant and $\sigma_8 = 0.8$. Fig. 1 offers a visual impression of the difference between the final results from the PZ (panels to the right-hand side) and PM simulations (panels to the left-hand side). In the top panels, the final distribution of objects in the PZ approximation is seen to follow closely the particle distribution in the PM code. This impression is further confirmed by the contour maps of the density fields in the bottom panels. The general agreement is impressive. The density fluctuations in the PZ are slightly of larger amplitude but this maybe due to cosmic variance. In Fig. 2, we also plot the density correlation functions obtained from PZ runs and a PM simulation. The solid line is the mean correlation computed from the mean of
Figure 1. A visual comparison between results of the PZ approximation (right-hand side) and a PM N-body code (left-hand side) run with the same initial conditions for 256^3 particles in a box of 64 h^{-1} \text{Mpc} on the side. Top: particle (object for PZ) distributions in a slice of 3.2 h^{-1} \text{Mpc} in thickness (for the PM only a random subset of all the particles is shown). For the PZ, each object is represented as a filled circle with radius proportional to the mass. Bottom: contours maps of log_{10}(density) in the same slice. The density fields are smoothed with a Gaussian window of a width of 1.125 h^{-1} \text{Mpc}. The thin solid and dashed lines are density contours above and below the mean, respectively. Thick solid lines indicate mean density contours. The contour spacing is 0.18.

Figure 2. Density correlation functions computed from the PZ and the PM simulations, as indicated in the figure. The mean of correlation functions from 60 PZ runs (each of 512^3 particles in a box of 128 h^{-1} \text{Mpc} on the side) is shown as the solid line. The attached error-bars are 1σ. For this comparison, we use a PM simulation of 256^3 particles in a box size of 512 h^{-1} \text{Mpc} on the side.

60 PZ runs (each of 512^3 particles in a box of 128 h^{-1} \text{Mpc} on the side), while the dashed is computed from the output of a single PM simulation of 256^3 particles in a box of 512 h^{-1} \text{Mpc} on the side. The 1σ error-bars attached to the PZ curve are estimated using the bootstrap method as follows. We generate 500 sets of simulations where each set contains 60 simulations picked randomly out of the 60 original simulations (i.e. some of these simulations could be selected more than once). For each set, we compute the mean correlation and the errors are estimated as the standard deviations between the mean correlations of the 500 sets.

The bump in \xi(r) in Fig. 2 at scales smaller than 2 h^{-1} \text{Mpc} (also visible in Fig. 3) is due to the finite resolution in the simulations. Therefore, we will base our conclusion on correlations on scales larger than 2 h^{-1} \text{Mpc}.

Objects (‘haloes’) in a PZ simulation are point-like, and are identified using different criteria than haloes in full N-body simulations. Therefore, we expect only a rough agreement between the mass functions of haloes (number density versus mass) computed from PZ simulations and full dynamics. We compared the abundance of objects versus mass in the PZ runs with the analytic predictions of Sheth & Tormen (2002) and Press & Schechter (1974) for the halo mass function. The transfer function used in these predictions is taken from Bardeen et al. (1986) with a slope of \alpha = 1 for the primordial power spectrum.

Overall, there is only a qualitative agreement between PZ and the analytic expressions. For masses \(4.3 \times 10^{11} h^{-1} M_{\odot}\), the PZ simulation agrees with PS and ST. However, for more massive haloes, the PZ overestimates abundance up to a factor of 2 for masses \(10^{13} h^{-1} M_{\odot}\). The difference is reduced as we go to higher masses until it disappears at \(6 \times 10^{13} h^{-1} M_{\odot}\). At higher masses, PZ falls short of the analytic expressions by a factor which increases with mass.

4 RESULTS

The merging history of an object (‘halo’) in our implementation of the PZ approximation is readily provided. We consider only haloes containing more than 100 particles (\(4.3 \times 10^{11} h^{-1} M_{\odot}\)) at the final time (\(z = 0\)) and define the formation time of a halo as the redshift at which it has acquired half of its final mass (Gao et al. 2005).

We use the correlation functions to probe the clustering properties of haloes. In Fig. 3, we plot the correlation functions, \xi(x), as a function of separation, \(x\), for haloes in three mass ranges in the left-hand side, middle and right-hand side columns, respectively. The dashed (dotted) lines in the top, middle and bottom panels, respectively, correspond to 10, 20 and 30 per cent oldest (youngest) haloes. The solid lines in all panels are identical and represent the correlation function of the mass density field. In each panel, the halo correlations are shown by two curves representing \pm \sigma deviations computed using the bootstrap method, as outlined in Section 3.

The dependence of the correlation function on the formation time is clear for all mass ranges shown in the figure. The bias persists even between the 30 per cent youngest and 30 per cent oldest haloes.

We use the difference between the correlation functions of old and young haloes to quantify the assembly bias at various separations. We determine the bias parameter \(b\) in separation range \((x, x + \Delta x)\) by minimizing the quantity (Gao & White 2007)

\[
\int_{\Delta x} dx \left[ \log \xi_{\text{old}} - \log (b^2 \times \xi_{\text{young}}) \right]^2.
\]

Fig. 4 shows the bias as a function of halo mass, for various separations. For masses \(\lesssim 3 \times 10^{12} M_{\odot}\), the bias is about 1.7 and is similar for all separations considered here. The error-bars are large at separations \(> 10 h^{-1} \text{Mpc}\) and we cannot detect an increase in the bias as claimed by Gao et al. (2005). The bias weakens with increasing halo mass, but remains statistically significant only for the
10 per cent old/young haloes, at separations $\lesssim 8 \, h^{-1} \text{Mpc}$. The figure shows that the mass scale $2-3 \times 10^{12} M\odot$ marks a mass threshold above which assembly bias weakens, for all separations. This threshold is close to the non-linear mass scale $M^\star$ defined as the mass scale over which the rms of density fluctuations is 1.69. For our initial conditions $M^\star \approx 5 \times 10^{12} \, h^{-1} \text{M}_{\odot}$.

Assembly bias may be caused by different environments of old and young haloes. We have experimented with cross-correlating the bias with several statistical measure of the environment. The most relevant measure that we find is the ‘dimensionality’ of the density field in regions near halo particles at the initial time. This parameter is an indicator of the geometry of the structure developing at later times in those regions. We show here that halo ages are strongly correlated with the ‘dimensionality’ of initial fluctuation field as defined by

$$\eta = \frac{\lambda_1 + \lambda_2 + \lambda_3}{\sqrt{\lambda_1^2 + \lambda_2^2 + \lambda_3^2}},$$  

(3)

where $\lambda_i$ is the eigenvalues of the tensor $\partial \theta / \partial \varphi$. At the centres of spherical, cylindrical and planar perturbations $\eta$ obtains the values $\eta = \sqrt{3}$, $\sqrt{2}$ and $\eta = 1$, respectively. We have computed the mean value $\eta$ as a function of distance from particles making up young and old haloes. The results are plotted in Fig. 5. Solid and dotted lines, respectively, show $\eta$ for old and young haloes (two lines representing $\pm \sigma$ deviations from the mean, calculated as explained in Section 3). This figure shows clearly that young haloes have an average higher dimensionality than old ones.

5 CONCLUSIONS

We have shown that assembly bias of haloes persists even in a simplified description of gravitational dynamics like the PZ approximation. The PZ approximation prevents the coasting away of particles in multistreaming regions by coalescing objects that have come within a critical distance of each other. The PZ is fast, simple to implement and readily provides object merging trees. This allows us to study assembly bias in a large number of simulations [60 simulations, each of $512^3$ particles in a $(128 \, h^{-1} \text{Mpc})^3$ cubic box]. The magnitude of the bias is comparable to that found in full simulations. This implies that highly non-linear effects such as mass loss from haloes in the vicinity of larger mass concentrations, may not be the dominant driver for assembly bias.

We intend to apply the PZ scheme to the initial conditions used in the millennium simulation (Springel et al. 2005) and compare the associated assembly bias with the result of Gao et al. (2005). This will yield a better quantitative assessment of the role of highly non-linear effects.

We have found a strong correlation between halo ages and the dimensionality of the nearby initial configuration. Young haloes tend to form in regions of higher initial dimensionality than old haloes. This is explained by the dependence of collapse time on
Figure 4. Square root ratio of clustering amplitude of old to young haloes as a function of their mass at various separations, as indicated in the panels. Solid, dotted and dashed curves, respectively, correspond to 10, 20 and 30 per cent oldest/youngest haloes. Error-bars (1σ) are plotted only for the solid lines. The value of $M_\star$ corresponding to our initial conditions is $5 \times 10^{12} \, h^{-1} M_\odot$.

Figure 5. The mean dimensionality parameter, $\eta$, as a function of separation from particles making up young (dotted blue lines representing ±σ deviations from the mean) and old haloes (solid black lines), all for 10 per cent oldest/youngest haloes.
dimensionality – a spherical perturbation collapses slower than a planar perturbation with the same initial density (Bertschinger & Jain 1994). Therefore, assembly bias would be explained if one could show that regions of lower dimensionality are more correlated than those of higher dimensionality. This problem could easily be tackled numerically using realizations of random Gaussian fields.
