ABSTRACT

Introduction: Deep transcranial magnetic stimulation (dTMS) utilizes different H-coils to study and treat a variety of psychiatric and neurological conditions with identifiable brain targets. The availability of this technology is dramatically changing the practice of psychiatry and neurology as it provides a safe and effective way to treat even drug-resistant patients. However, up until now, no effort was made to summarize the different types of H-coils that are available, and the conditions for which they were tested.

Areas covered: Here we assembled all peer reviewed publication that used one of the H-coils, together with illustrations of the effective field they generate within the brain. Currently, the technology has FDA clearance for depression and European clearance for additional disorders, and multi-center trials are exploring its safety and effectiveness for OCD, PTSD, bipolar depression and nicotine addiction.

Expert commentary: Taken together with positive results in smaller scale experiments, dTMS coils represent a non-invasive way to manipulate pathological activity in different brain structures and circuits. Advances in stimulation and imaging methods can now lead to efficacious and logical treatments. This should reduce the stigma associated with mental disorders, and improve access to psychiatric treatment.

1. Introduction

Over the past half century, advances in the field of psychiatry increased the physician’s toolbox exponentially. New classes of pharmacological drugs were developed, electroconvulsive therapy (ECT) protocols were optimized [1], and focal brain stimulation techniques were invented [2]. Most importantly, many psychiatric symptoms have now identifiable functional alterations in specific brain regions and circuits due to advances in functional imaging [3,4]. Methods, such as MRI, fMRI, positron emission tomography, and single-photon emission computed tomography relate specific disorders and symptoms to specific brain areas with altered activity or volume [5]. This allows techniques such as deep brain stimulation (DBS) or transcranial magnetic stimulation (TMS) to target specific networks that are known for their affected activity in a specific disorder.

One condition for which significant progress has been made is major depression disorder (MDD). MDD is a commonly occurring disorder, and with a lifetime prevalence of 17%, it ranks as the second leading cause of disability according to World Health Organization (WHO) [6]. Patients diagnosed with MDD show dysregulation in several brain regions, including hypometabolism in regions, such as the dorsolateral prefrontal cortex (DLPFC) and the cingulate cortex (ACC), and abnormal overactivity in the amygdala, basal ganglia, and thalamus [7]. Despite the availability of psychotherapy and over four classes and 30 distinct pharmacologic agents, a large portion (32–52%) of the MDD population are still considered treatment resistant [8,9]. Taken together with MDDs relapsing nature and the tolerance that may develop to formerly successful pharmacotherapy [10], non-drug strategies are required for the management of this disorder. Over the years, different methods have been developed for that purpose but, side by side with their unique advantages, all methods also have their own drawbacks [11]. Among the available brain stimulation technologies, ECT is still considered to be the most effective method, with over 70% remission rate [12,13]. Yet, the procedure is associated with side effects and continues to be the most stigmatized treatment available in psychiatry, a fact that hinders people from pursuing it [1]. Thus, ECT is considered to be the ‘last resort’ and is used only for severely drug-resistant patients [14]. DBS has also been shown to alleviate depressive symptoms in drug-resistant MDD patients [15–21]. However, DBS also has important drawbacks, as it involves a complex surgical intervention (i.e. drilling in the skull with the risk of infection), requires replacing the subcutaneous battery periodically, and has a high overall cost [22]. The optimal targets for DBS are still not known, and although the background suicide rate in this population is elevated there is controversy about DBS causing suicidal ideations [7,23–27]. Conventional TMS, being a non-invasive technique, does not have the above disadvantages and has been shown to effectively treat MDD in moderately drug-resistant patients [28–30]. However, conventional TMS only allows stimulation of focal targets just below the skull and, without navigation, conventional repetitive TMS (rTMS) misses the target in 27–32% of patients [31,32] (See Box 1).

In an attempt to address these limitations, deep TMS (dTMS) was introduced [33,34]. dTMS includes all the benefits of TMS (no
need for hospitalization or anesthesia and negligible side effects \([11]\) with the advantage of stimulating deeper brain targets with less focal distribution of the electric field. Similar to the conventional TMS technique, dTMS utilizes brief magnetic pulses to induce targeted neuronal depolarization in the brain using Faraday’s law of electromagnetic induction \([35]\). Usually, trains of pulses delivered at high frequency stimulation (>5 Hz) lead to a facilitatory effect inducing increased neuronal excitability (long-term potentiation; LTP-like effect) while low frequency (<1 Hz) induces reduction in neuronal excitability (long-term depression; LTD-like effect) \([36,37]\); thus, hypo- or hyper-activity of specific brain areas can be modulated. However, conversely to conventional TMS coils (e.g. figure-of-8 or round), which directly stimulate targets up to ~1 cm beneath the surface of the skull, dTMS can simulate up to ~4 cm beneath the surface of the skull, depending on the specific H-coil being used \([38]\). This increased stimulation depth is achieved due to the multiple windings in multiple planes inside the H-coil helmet. The magnetic fields of these windings sum together and improve the depth penetration of the electromagnetic field without the need for increased electric intensity. Although deep stimulation can also be accomplished with a large circular coil or a double cone coil, their electromagnetic field decays more rapidly and to reach significantly deep targets much higher intensities must be used on the surface \([36,39]\); intensities that can be unpleasant and potentially unsafe for the patient. Finally, the H-coils stimulate larger areas, i.e. ~17 cm\(^2\) of the brain tissue with the H1 compared to ~3 cm\(^2\) with conventional figure-8 coils, when both are operated at 120% of motor threshold (MT). This volume difference represents hundreds of millions of neurons and many more pathways, eliminates the need for imaging and neuronavigation and making the treatment less costly.

### 1.1. dTMS in the clinic

In the United States, dTMS using the H1-coil is cleared for the treatment of unipolar major depression that has failed any number of medications. In Europe, dTMS using the H1-coil is cleared for the treatment unipolar depression, bipolar depression, negative symptoms of schizophrenia, and post-traumatic stress disorder (PTSD), while several other H-coil versions designed to target other brain networks are cleared for the treatment of Alzheimer’s disease, chronic pain, smoking cessation, obsessive compulsive disorder (OCD), autism, Parkinson’s disease, stroke rehabilitation, and multiple sclerosis (MS).

### 1.2. Clinical considerations

In the United States, anyone can purchase a dTMS device but it can only be used under the prescription of a physician (usually a psychiatrist or a neurologist). At the present time about 90% of all dTMS is done for the treatment of medication refractory unipolar major depressive disorder (treatment resistant depression; TRD). However, one may also treat patients for off label conditions. The assessing physician’s responsibility is to search current literature to determine if there are any new protocols for treatment of the relevant disorder, or for the treatment of comorbid conditions (e.g. depression and MS fatigue, depression and PTSD, and depression and pain).

Prior to administering dTMS to a patient, informed consent must be obtained from the patient or their legal guardian. In addition to explaining the procedure, the process includes an explanation of the risks, benefits, and alternatives. The risks or potential side effects of dTMS include headaches, facial pain, tooth pain, or neck pain usually just during the procedure but it may also occur between the procedures as well. Patients can premedicate with an analgesic, and the pain typically decreases on sequential treatments. If ear plugs are not worn or if they fall out, the repetitive loud noise from dTMS can cause permanent hearing loss or tinnitus. In rare cases, patients receiving dTMS can have generalized neuronal excitation beyond the site of stimulation resulting in a seizure. The risks of a seizure occurring are highest in patients with pre-existing epilepsy, changing medication dosage without rechecking the motor threshold, alcohol intake or sleep deprivation. Seizures from dTMS have always stopped on their own and only occurred during the treatment, dTMS does not cause epilepsy. Alternatives to dTMS in the case of TRD include ECT or combinations of medications.

### 1.3. Treatment protocol

dTMS practice protocols are similar to the ones that are used with conventional TMS. In the case of MDD, patients are scheduled for a diagnostic evaluation with a psychiatrist that reviews their medical history, documents the current symptoms of depression, prior treatment trials, and recommends a course of dTMS, which would entail an acute course of dTMS treatments administered five days a week. Each treatment session includes 55 trains of 36 pulses (for a total of 1980 pulses per session) delivered over 20 min at

---

**Box 1. Alternative non-pharmacological somatic treatments**

- Electroconvulsive therapy (ECT): The first device-based treatment to become available for psychiatric disorders. During treatment, electric current passes through electrodes placed at precise locations on the head, causing a seizure that lasts generally less than 1 min.
- Magnetic seizure therapy (MST): Similar to ECT it induces a seizure, but conversely to ECT it uses magnetic pulses instead of electricity to stimulate the brain. MST appears to have less cognitive side effects than ECT.
- Deep brain stimulation (DBS): A generator implanted in the chest control electrodes implanted in a specific brain area. Stimulation is continuous and its frequency and intensity can be adjusted to the individual. The targets for OCD and Parkinson’s are known, for depression they are still controversial and under investigation.
- Vagus nerve stimulation (VNS): A generator implanted in the chest sends electrical pulses to the left vagus nerve. VNS was approved in 2006 for depression but is not covered by insurance due to low efficacy rates. It is covered for the treatment of refractory epilepsy.
- Conventional or superficial TMS: Conventional TMS coils induces a very focal effective electric field up to 2 cm from the coil. Besides treatment, conventional TMS with neuronavigation is useful in single pulses for presurgical brain mapping.
- Transcranial electrical stimulation (tES): Encompasses all forms of non-invasive application of electrical currents to the brain using electrodes on the head. tES includes, among others, cranial electrotherapy stimulation (CES) and transcranial direct current stimulation (tDCS), which induce subthreshold electric fields in the brain. tES may be helpful for non-treatment resistant patients.
18 Hz and intensity of 120% relative to the patient’s resting motor threshold (MT) [40]. The individual MT is re-measured at least once a week or when a medication is changed, by determining the minimal intensity for which a single pulse activates the hand motor cortex in 5/10 trials (evident as a movement of the limb or with electromyography). In many cases, even patients that do not improve after 30–40 sessions may reach response (50% improvement) with additional dTMS sessions [40]. Alternatively, the physician can consider increasing the number of pulses. High rates of remission and response were found in severe TRD patients who were treated with 3000 dTMS pulses per session [41] and 4000–6000 pulses were effective for patients with schizoaffective depressive phase and patients who failed ECT [42,43]. When the patient goes into remission or has a sustained improvement, the patient should continue treatment twice a week for a period of three months. Once the patient goes into remission from dTMS, they are considered future first-line dTMS patients. When these patients relapse or have recurrence of their depression, they should be immediately retreated with dTMS instead of trying a new medication. In addition, if they have several relapses a year, maintenance dTMS may be a preferred treatment. Maintenance dTMS is done once a week, after a period of 3 months of stability on twice a week treatments.

1.4. Technical considerations

The dTMS device is comprised of a rolling cart, which contains a stimulator and an air-cooling system for the coil, and a positioning arm attached to the side of the cart holding the H-coil inside of a cushioned helmet (Figure 1). The device can fit in the corner of a room, and any chair can be used for treatments; thus, any room can be used as a dTMS treatment room. The machine requires two NEMA 5–20 A outlets on different fuses and one 15 A outlet to plug the machine into, which almost any office room has. When the machine is used all day, the room it is in will become significantly warmer than the rest of the office and may require its own air-conditioning zone. Alternatively, the back of the cooling unit can be vented out of the treatment room.

Every cart can hold several positioning arms and hence several different H-coils that target different brain areas for different indications. Every helmet can technically hold several H-coils, and during clinical trials every helmet has a corresponding sham H-coil encased in the same helmet. The sham coil induces only a negligible sub-threshold field in the brain while making an identical noise and inducing some scalp sensation [44]. The research version of the dTMS device has an electronic card reader and interface module that operate on each patient’s treatment card determining whether the sham or active coil in the helmet should be used for that specific treatment. The operator uses an operator card to find the MT, and then moves the helmet to the treatment position. At this point, a randomized patient card is used to administer repetitive pulses. This maintains the double blind condition necessary for research trials, where both the operator and the patient can not tell whether an active or sham treatment is delivered (as the two coils sound and feel similar to the operator who may be holding the helmet from the outside).

1.5. The induced effects of dTMS

The H1-coil that is used for the treatment of MDD was designed to induce activation of left and right lateral and medial prefrontal cortex structures, with a preference to the left hemisphere (Figure 2). The safety and efficacy of the H1-coil in MDD were demonstrated in several clinical trials (as detailed in Table 1), including a large prospective multicenter study [40], which formed the basis for US FDA approval for the treatment of MDD in the United States. The safety and efficacy of the H1-coil was also demonstrated in bipolar disorder [45], negative symptoms of schizophrenia [46,47], and using a more medial location also in PTSD [48]. Preliminary studies showed effectiveness for the H1-coil also in alcoholism (and associated dysthymia) [49–51] and even in migraine [52] (Table 1). Several other H-coils were developed in order to affect different brain networks and hence treat different conditions (Table 1). To create Table 1, all of the peer-reviewed literature with the term deep transcranial magnetic stimulation was reviewed by each the authors using PubMed with and without a clinical trial filter. Centers that have dTMS coils are surveyed by the manufacturer for peer-reviewed publications that may not have been indexed in Pubmed as well as ongoing clinical research activity, and this data was reviewed as well. Finally, all of the ongoing single and multisite clinical trials were added. The

publications were discussed by the authors as a group, and the coils were listed with corresponding disorders with the level of evidence stated explicitly in the table.

The effects of the H-coils are best understood through electrical field diagrams (Figures 2–15). These diagrams are generated by placing each coil over a plastic head model filled with saline solution and measuring the induced fields at every point with an oscilloscope. In the diagrams, red pixels indicate regions where the induced field intensity is above the threshold for neural activation (100 V/m). The maps for each coil are generated while the coil is located above the specific treatment location and the intensity is set per the relevant recommended treatment protocol. As can be observed, there is overlap in the areas that coils stimulate, and coils can be moved from their intended-designed position to another location to achieve a similar effect as another coil (i.e. moving the H7 coil from the PFC-ACC posteriorly to the motor cortex will result in a coil that effectively stimulates both lower extremities).

1.6. dTMS operators
The field of TMS technicians is just evolving, and it will continue to evolve as the devices and indications evolve.

Figure 3. Colored field maps for the H2-coil indicating the absolute magnitude electrical field in each pixel at 120% of hand motor threshold, for 16 coronal slices 1 cm apart. Red pixels indicate regions with field intensity above the threshold for neuronal activation. Full color available online.

Figure 4. Colored field maps for the H3-coil indicating the absolute magnitude electrical field in each pixel at 120% of foot motor threshold, for 9 coronal slices 1 cm apart. Red pixels indicate regions with field intensity above the threshold for neuronal activation. Full color available online.
Currently, most dTMS operators have a bachelor’s degree and an interest in neuroscience or patient care. Operators have much more frequent contact with patients than receptionists and are similar to behavioral health technicians or nurses. The manufacturer trains and certifies operators on the device. Operators should be trained in first aid and CPR; and must be comfortable recognizing and making initial steps to deal with a seizure, because this is the only significant safety risk with dTMS, even if a very rare one [80]. In addition, as they interact with depressive patients, they should be prepared for the possibility of their patients attempting suicide. This should be discussed with the operators when they are treating patients with prior suicide attempts. Operators should be observant, comforting and not alarming to the patients. Operators are also responsible for administering specific rating scales to patients and keeping accurate records of patient treatments. Finally, some off-label dTMS protocols require an intimate knowledge of patient symptoms, because the patient’s symptoms need to be provoked before the treatment (OCD, PTSD, addictions) [44,48,72]

1.7. Financial considerations

Almost all of the TMS centers in the United States today are part of psychiatric offices, and each dTMS system can easily treat two patients per hour. Typically, one operator treats one patient at a time on one machine per room. The income from dTMS comes from the procedural fee or, in the case of a facility, from the facility and procedural fee. There are three TMS CPT codes, which are widely covered by insurance across the country for MDD patients: 90867, 90868, and 90869. Therapeutic rTMS treatment; initial, including cortical mapping, motor threshold determination, delivery and management (90867) is reported only once per treatment course. Subsequent delivery and management (90868) is reported 20–40 times per treatment course series. Subsequent motor threshold re-determination with delivery and management (90869) is reported no more frequently than once a week or when medication dosages are altered [80].

Medicare and some commercial insurers have no preauthorization process and the patient can start treatment immediately. However, several commercial insurance companies require a preauthorization process at which time they approve an initial course of acute treatments with the expectation that periodic rating scales will be completed by the patient and an assessment will be done by the physician at baseline and follow up.

The patients usually come from the clinic’s existing patient population, after having failed or been intolerant to one or more antidepressant medications (because that is what commercial insurance and medicare covers). However, as dTMS devices are not that costly, it is entirely possible to have a self-pay dTMS clinic. The dTMS system costs are generally

Figure 7. Colored field maps for the H6-coil indicating the absolute magnitude electrical field in each pixel at 120% of hand motor threshold, for 11 coronal slices 1 cm apart. Red pixels indicate regions with field intensity above the threshold for neuronal activation. Full color available online.

fixed. This includes the device, a maintenance plan, insurance on the device and the practice, rent, marketing fees and salary for an operator. The variable costs are relatively nominal and they include earplugs and soft caps for the patients and electricity. The dTMS system is currently available in any of three formats: purchase the system with no per use charges with a 1-year warrantee that can be extended every year for a fee. Alternatively, it is available for a 4-year lease with no per use charges with the maintenance fee included. Finally, a hesitant physician can enter a risk sharing model, where the physician pays per use charges and there is no maintenance fee.

1.8. Legal considerations

All of the patient information is available in the patient manual, and should be made available to patients, similar to the package insert that comes along with a medication. Legally this is sufficient and the FDA does not require a specific written consent for TMS. However, most US TMS centers develop brief consent forms that specify rTMS is currently only approved for resistant unipolar MDD, but used for many other conditions on an off label basis. It outlines the potential risk of a temporary seizure, reminds to use hearing protection at peril of permanent hearing.

Figure 9. Colored field maps for the H8-coil indicating the absolute magnitude electrical field in each pixel at 120% of hand motor threshold, for 14 coronal slices 1 cm apart. loss, mentions temporary head/face/tooth/neck pain and availability of analgesic prophylactics, discusses alternative treatments, such as ECT or polypharmacy, and the fact rTMS has only been studied in humans since the 1990s, and there may be adverse long-term effects not yet known. Some consent forms also inform patients that their treatment data is kept in a separate database in an anonymous fashion for outcomes research.

2. Conclusion

Mental illnesses carry a stigma that affects patients, family members and even psychiatrists. This discrediting is present in every country, and it has not disappeared despite tremendous advances in the field of psychiatry over the last half century. One potential reason is that brain abnormalities are hidden from the naked eye, and another is that these chronic and complex conditions significantly affect behavior. Taken together with the fact that psychopharmacologic interventions do not have very clear and logical explanations for their mechanism of effect, the result is that patients are often blamed for their illness, which rarely occurs in general medical conditions [81–84]. However, this trend is slowly shifting its direction. Depression is much more accepted in the general population, evident by the growing number of people seeking treatment for this condition; Drug and alcohol addictions are gradually recognized as brain

Figure 11. Colored field maps for the H10-coil indicating the absolute magnitude electrical field in each pixel at 100% of foot motor threshold, for 14 coronal slices 1 cm apart. diseases by law-enforcement; and conditions such as ADHD or autism are diagnosed in progressively increasing rates. This shift is related to advances in functional imaging and focal brain stimulation that allows the identification and modification of altered activity in specific brain areas for specific psychiatric conditions and symptoms. This is bridging the theoretical gap between diseases of the mind-psychiatric illness, and diseases of the brain-neurological illnesses for both patients, caregivers, and the general population [85,86]. Thus, advances in bioengineering that enabled non-invasive modulation of altered brain activity (such as TMS and dTMS), making efficacious and logical treatments widely available to psychiatric patients, are reducing the stigma of mental illness as a whole. As a consequence, more people are now searching for treatments for their conditions, and a broader spectrum of alternatives is available to meet the specific needs of the individual.

3. Expert commentary

The most comparable technology to compare dTMS to is conventional TMS with the figure-8-shaped coils. They are both outpatient procedures with no significant adverse event profiles, only local discomfort and rare incidence of seizure. Unfortunately, there has been no head to head study comparing the two technologies. The advantages of dTMS to conventional TMS are theoretical, clinical, and practical. The
theoretical advantages of dTMS are derived from the ability of the H-coil to stimulate much larger and deeper volumes of neuronal tissue. The difference is notable whether one uses mathematical modeling in spherical model of the head [87,88], mathematical modeling in an anatomically correct model of the head [89–91], or measures the depth of stimulation in saline filled head [39,92,93]. Clinicians are aiming at a target that they cannot see without concomitant functional imaging and neuronavigation, a shotgun is likely to have greater efficacy than a rifle. The clinical advantages of dTMS are derived from comparing the results of the multisite double blinded randomized controlled trials leading to FDA clearance of the devices. The standardized effect size after 4 weeks for the H1 was 0.76, and for the figure-8 coil, it was 0.36–0.56 depending on the scale. After 4 weeks, the odds ratio for remission with the H1 was 2.83 compared to 1.1–1.16 with the Figure 8 [40,94]. The practical advantages of dTMS mainly relate to the time of treatment. The dTMS system has an active air cooling system which allows the operator to complete treatments in 20 min. It is easy to run the system continuously all day while treating two patients per hour. The motor threshold is easy to find, because of the large area of stimulation of the coil. Compared to a figure-8 coil, the shortest time of stimulation is 37.5 min, and it takes a long time to map the motor threshold. A busy office can use one dTMS system and one operator to replace two figure-8 systems and operators. Although there have not been any head to head studies yet, there are two published case series from unbiased sources demonstrating better clinical outcomes for the patients they treated with dTMS [95,96].

Where does dTMS fit in right now, and what coils should a dTMS center get? The primary disorders a non-research dTMS center will be treating are psychiatric. The H1-coil is the most tested coil, and every dTMS center should have one. It should be used for patients with depression who have failed any number of medications before trying ECT, and it can be used after ECT as a maintenance strategy in lieu of ECT maintenance [97,98]. There is early data suggesting that higher numbers of pulses may be helpful for patients with psychotic depression or schizoaffective disorder depressive phase as well as patients who failed ECT [42,43], the H1 is helpful for the negative symptoms of schizophrenia [46,62]. Additional coils with significant clinical evidence and ongoing multisite clinical trials are the H4 for patients with addiction and the H7 for patients with OCD and PTSD.

4. Five-year view

At present, the field of TMS is focused on targeting one brain area at a time, such as the left DLPFC cortex in depression or the ACC in OCD. As understanding of brain functioning advances, the more evident it is that complicated behaviors are mediated by connected neural networks [85,99]. Thus, it is unlikely that stimulation or inhibition of one area in the brain is the optimal approach to induce normalization of neuronal functioning in all patients. Thus, the future of non-invasive neuromodulation requires the use of a multichannel stimulator with interconnected coils [100] to affect the relevant neuronal networks during tasks and at rest in pathological conditions, and to induce synchronized and optimized differential protocols to different brain regions. In that way, modification of activity can also be induced using paired associative stimulation [101] rather than by trains of pulses. This procedure may greatly affect the patient’s treatment experience as it requires significantly less pulses and a much lower frequency of administration (0.2–0.25 Hz). As a result, the treatment can be painless and free of any side effects. Such a technology, a multichannel stimulator, and multisite H-coils, has been recently presented [100], and preliminary results of ongoing experiments are expected in the near future.

Another issue that is expected to progress in the near future is the individualization of the treatment and the ability...
to predict treatment outcome prior to its initiation. More specifically, it is expected that future treatment will be based on the individual’s brain activity, measured by EEG or fMRI prior to administration of TMS. This prospect is based, at least in part, on preliminary and yet to be published data that demonstrate how specific brain activity prior to treatment predicted not only response (yes/no) but also the magnitude of that response in MDD or ADHD patients.

Key issues

- dTMS is a novel non-invasive deep brain stimulation technique
- dTMS has FDA clearance for the treatment of MDD
- dTMS is an emerging treatment for several brain-related conditions
- Different coils are used for different indications, or to target different neuroanatomical structures

Information resources

- dTMS H-coils manufacturer’s web site - http://www.brainsway.com/

Funding

This paper was funded by Brainsway Ltd.

Declaration of interest

A. Tendler is the chief medical officer of Brainsway and has a financial interest in Brainsway, the manufacturer of the dTMS H coils. Y. Roth and A. Zangen are the inventors of the H Coil and founders of Brainsway. They have a financial interest in Brainsway, the manufacturer of the dTMS H coils. The authors have no other relevant affiliations or financial involvement with any organization or entity with a financial interest in or financial conflict with the subject matter or materials discussed in the manuscript apart from those disclosed.
