Disorder-induced tail states in a gapped bilayer graphene

V. V. Mkhitaryan and M. E. Raikh
Department of Physics, University of Utah, Salt Lake City, UT 84112

The instanton approach to the in-gap fluctuation states is applied to the spectrum of biased bilayer graphene. It is shown that the density of states falls off with energy measured from the band-edge as \( \nu(\epsilon) \propto \exp(-|\epsilon/\epsilon_i|^{3/2}) \), where the characteristic tail energy, \( \epsilon_i \), scales with the concentration of impurities, \( n_i \), as \( n_i^{2/3} \). While the bare energy spectrum is characterized by two energies: the bias-induced gap, \( V \), and interlayer tunneling, \( t_\perp \), the tail, \( \epsilon_i \), contains a single combination \( V^{1/3} t_\perp^{2/3} \).

We show that the above expression for \( \nu(\epsilon) \) in the tail actually applies all the way down to the mid-gap.

I. INTRODUCTION

Several experimental studies of electronic properties of graphene bilayers were recently reported in the literature.\(^1\,2\,3\,4\,5\,6\,7\,8\,9\,10\,11\,12\,13\,14\,15\,16\,17\,18\,19\,20\,21\). One of these consequences is that biased bilayer responds to disorder as a “normal” semiconductor, i.e., impurities give rise to the tails of the density of states which extend into the gap from the bottom of conduction and from the top of the valence band. Such in-gap localized states are especially relevant to the experiment Ref. 8, where the inelastic transport over these states has been observed. This raises a theoretical question about the shape of in-gap fluctuation tails in bilayers and their dependence on the disorder strength. The only paper on biased graphene bilayers with impurities that we are aware of is Ref. 13. This paper studies not the tails, but rather disorder-induced smearing of the band-edges. Also, the numerical results for the density of states in the gap region are presented in Ref. 13 for particular values of impurity concentration, \( n_i \), so that the general dependence of the magnitude of smearing on \( n_i \), as well as on the interlayer bias, \( V \), was not established.

In the present paper we study analytically the density of disorder-induced localized in-gap states in bilayer graphene. The reason why classical results\(^23\,24\,25\) for the fluctuation tails do not directly apply to this situation, is a peculiar structure of the bare energy spectrum shown in Fig. 1. In particular, the minimum (maximum) of the electron (hole) dispersion is located at finite momentum\(^10\), \( p_0 \). Also, at energies of the order of the gap, the dispersion law is not quadratic, but rather \( \epsilon(p) \propto p^4 \). These two features naturally define two regimes of disorder-induced broadening of the density of states:

\( \epsilon(p) \propto p^4 \)

(i) Weak disorder. The magnitude of smearing in this regime is smaller than the depth of the minimum in

\[
\langle U(r)U(r') \rangle = \gamma \delta(r-r'),
\]

(iii) Strong disorder. The mexican-hat-structure in Fig. 1 is completely smeared. In this regime, the in-gap states are formed due to trapping of electrons (holes) with quartic dispersion by certain disorder configurations.

Below we demonstrate than in both regimes the magnitude of smearing, \( \epsilon_i \), is proportional to the combination \( n_i^{2/3} V^{1/3} \). Clearly, for the gap to be resolved, the applied bias must exceed \( \epsilon_i \). This suggests that the threshold bias, for which \( V > \epsilon_i \) is proportional to the first power of \( n_i \). We find the shape of the density of states near the band-edges for two regimes by extending the instanton approach of Refs.\(^23\,24\) to the spectrum of a biased bilayer graphene. We restrict consideration to the case of short-range impurity potential, \( w(r) \), so that the correlator of the disorder potential is

\[
\langle U(r)U(r') \rangle = \gamma \delta(r-r'),
\]

\( \gamma \) being the instanton coupling constant.

\[ \epsilon(p) \propto p^4 \]
with
\[ \gamma = n_i \left[ \int d\mathbf{r} w(\mathbf{r}) \right]^2. \] (2)

We also assume that the bias is smaller than the interlayer tunneling constant, \( t_\perp \).

**II. BARE DENSITY OF STATES**

Due to interlayer hopping, the spectrum of the bilayer graphene becomes parabolic \(^9,10\), \( \epsilon(p) = \pm c^2 p^2 / t_\perp \), where \( c \) is the Dirac velocity in graphene. For "small" momenta, \( cp < t_\perp \), the gap opens upon applying the bias, \( V \), between the layers. For \( V < t_\perp \), the low-energy Hamiltonian of the bilayer graphene can be reduced to the \( 2 \times 2 \) matrix
\[ \mathcal{H} = \begin{pmatrix} \frac{V}{2} & \frac{c^2 p}{t_\perp} - \frac{c^2 (p_x + ip_y)^2}{t_\perp} \\ -\frac{c^2 (p_x - ip_y)^2}{t_\perp} & -\frac{V}{2} \end{pmatrix} \] (3)
which yields the spectrum
\[ \epsilon^\pm(p) = \pm \left[ \frac{V}{2} + \frac{c^2 p}{t_\perp} \right]^2 \pm \frac{c^4 p^4}{t_\perp^2}. \] (4)
It is seen that in addition to opening the gap, finite bias, \( V \), leads to negative effective mass at small momenta. Disorder affects the energy domains \( |\epsilon(p) - V/2| \ll V \), close to the band edges. In these domains the spectrum can be further simplified to
\[ \epsilon^\pm(p) = \pm \left[ \frac{V}{2} + \frac{c^4 p^4}{t_\perp^2} \right]. \] (5)
where
\[ p_0 = \frac{V}{2c} \] (6)
is the minimum position, Fig. 1. In Eq. \( 5 \) we also took into account that \( V \ll t_\perp \). The eigenfunctions, corresponding to the two branches, have the form
\[ \chi^+_p(\mathbf{r}) \approx e^{ipr} \left( e^{2i\phi_p} - \frac{c^2 p^2}{t_\perp} \right); \quad \chi^-_p(\mathbf{r}) \approx e^{ipr} \left( e^{-2i\phi_p} \right). \] (7)
where \( \phi_p = \tan^{-1}(p_y/p_x) \) is the azimuthal angle of the vector \( p \). The minimal energy for the branch \( \epsilon^+ \) is
\[ \Delta = \frac{V}{2} - \frac{V^3}{16t_\perp^2}. \] (8)
Shifting the energy scale origin to \( \Delta \), for the bare density of states, \( n_0(\epsilon) \), we will have
\[ n_0(\epsilon) = \left( \frac{4t_\perp^2}{Ve^2} \right) \tilde{\nu}(\epsilon/\epsilon_m), \] (9)
where
\[ \epsilon_m = \frac{V^3}{16t_\perp^2}. \] (10)
is the depth of the minimum, Fig. 1, and the dimensionless function \( \tilde{\nu}(z) \) is defined as
\[ \tilde{\nu}(z) = \begin{cases} \frac{1}{\sqrt{z}}, & 0 < z < 1; \\ \frac{1}{2z}, & z > 1. \end{cases} \] (11)
Single-scale behavior of \( \tilde{\nu}(z) \) ensures that the magnitude of disorder-induced smearing of the band edges is defined by a single parameter for both weak- and strong-disorder regimes.

**III. WEAK DISORDER**

In the vicinity of the minimum at \( p = p_0 \), the dispersion law simplifies \(^13,15,19\) to
\[ \epsilon^\pm(p) = \pm \left( \frac{|p| - p_0}{2m} \right)^2; \quad m = \frac{t_\perp^2}{2Ve^2}. \] (12)

This expansion applies in the domain, \( (|p| - p_0) \ll V/c \), where \( \epsilon(p) - \epsilon(p_0) \) is smaller than the energy distance \( V^3/16t_\perp^2 \) between the minimum and maximum in Fig. 1. The eigenfunctions Eq. \( 7 \) simplify to
\[ \chi^+_p(\mathbf{r}) \approx e^{ipr} \left( e^{2i\phi_p} - \frac{V}{4t_\perp} \right); \quad \chi^-_p(\mathbf{r}) \approx e^{ipr} \left( e^{-2i\phi_p} \right). \] (13)

One-dimensional character of the spectrum is reflected in the \( \epsilon^{-1/2} \) behavior of the density of states Eq. \( 10 \) near the band-edge. The magnitude, \( \epsilon_t \), of disorder-induced broadening can be estimated from the following reasoning. The inverse scattering rate due to the disorder, calculated from the golden rule, is given by
\[ \frac{1}{\tau(\epsilon)} = \frac{\gamma}{\pi} n_0(\epsilon) = \frac{\gamma t_\perp V^{1/2}}{2\pi c^2 \epsilon^{1/2}}. \] (14)
Then the estimate for \( \epsilon_t \) emerges upon equating \( 1/\tau(\epsilon_t) \) to \( \epsilon_t \), yielding
\[ \epsilon_t = \left( \frac{V^{1/2} t_\perp}{c^2 \gamma} \right)^{2/3}. \] (15)
Note that the above consideration equally applies for weak disorder, \( \epsilon_t < \epsilon_m \), and strong disorder, \( \epsilon_t > \epsilon_m \). As follows from Eq. \( 15 \), the weak-disorder regime realizes for
\[ \epsilon \ll \left( \frac{V}{t_\perp} \right)^4. \] (16)
The fact that the fluctuation states in weak-disorder regime are composed essentially from the free states with
The solution of Eq. (18) has the form

$$\nu_0(x) = (2/x)^{1/2}. \nonumber$$

where the energy $\epsilon$ is defined as

$$\epsilon = E - \left(\frac{V}{2} - \frac{V^3}{16t_\perp^2} + \text{Re}\Sigma\right), \quad (20)$$

and the dimensionless function $A(x)$ satisfies the algebraic equation

$$A(x) = \sqrt{\frac{x + \sqrt{A(x)^2 + x^2}}{A(x)^2 + x^2}}. \quad (21)$$

The solution of this equation has the form

$$A(x) = \left(\frac{3^{1/2}2^{1/3} (3^{3/2} + 2^{5/3} x^{1/3})^{1/3} - 2^{2/3} x^{1/3}}{(3^{3/2} + 2^{5/3} x^{1/3})^{2/3} - 2^{2/3} x^{1/3}}\right)^{1/2}. \quad (22)$$

The density of states per spin and per valley can be expressed via $A(x)$ as

$$\nu(\epsilon) = \frac{1}{\pi} \text{Im}\Sigma(\epsilon) = \frac{1}{2^{5/3} \pi} \frac{V^{1/2} t_{\perp}^{1/2}}{\epsilon_t^{1/2} \epsilon_m^{1/2}} A\left(\frac{2^{5/3} \epsilon}{\epsilon_t}\right). \quad (23)$$

It is plotted in Fig. 2 together with the bare density of states.

Constraining low boundary of $\nu(\epsilon)$ in Fig. 2 is an artifact of the RPA. In reality it is smeared within the energy interval

$$\tilde{\epsilon}_t = \frac{\epsilon_t^{3/2}}{\epsilon_m^{1/2}} = \frac{4\gamma t_{\perp}^2}{V^{1/2}} \ll \epsilon_t, \quad (24)$$

which is much smaller than $\epsilon_t$. This smearing comes from non-RPA diagrams. Concerning the deep tail of $\nu(\epsilon)$, it is close to a simple exponent, namely

$$\nu(\epsilon) \propto \exp\left[-\frac{4|\epsilon|}{\tilde{\epsilon}_t \ln(\epsilon_m/|\epsilon|)}\right]. \quad (25)$$

The reason why this tail can be found analytically is again the fact that the wave functions of the fluctuation states have two spatial scales; they oscillate rapidly with period $p_0^{-1}$ and decay at much larger distances as exp($-\sqrt{2m}\epsilon r$). The tail states are very similar to those found in Ref. 28. The key steps of derivation of Eq. (24) are outlined in the Appendix.

IV. STRONG DISORDER

We now turn to the case of a strong disorder when $\epsilon_t > \epsilon_m$. The shape of the tail density of states in this case can be established from the following qualitative consideration. The probability density to find a fluctuation $U(\mathbf{r})$ is given by

$$\mathcal{P}\{U(\mathbf{r})\} = \exp\left[-\frac{1}{2\gamma} \int d\mathbf{r} U^2(\mathbf{r})\right]. \quad (26)$$
In order to create a localized level with binding energy, $\epsilon$, the magnitude of the fluctuation must exceed $|\epsilon|$, while the size cannot be smaller than the de Broglie wave length, $r_c$, of a free electron with energy, $\epsilon$, i.e.,

$$r_c = \frac{1}{p_c} = \left( \frac{c^4}{V t^2_\perp |\epsilon|} \right)^{1/4}, \quad (27)$$

where the last identity follows from the dispersion law $\epsilon(p) = c^2 p^2 / V t^2_\perp$. Now the integral $\int dr U^2(r)$ can be estimated as $c^2 r_c^2$. Substituting this estimate into Eq. (26) and using Eq. (27), we get

$$\nu(\epsilon) \propto \exp \left( - \frac{|\epsilon|^{3/2}}{\epsilon_t^4} \right). \quad (28)$$

The remaining task is to establish the numerical coefficient in the exponent of the instanton approach with the help of the instanton approach. Within this approach, one should solve the Schrödinger equation with potential, $U(r)$, which yields an eigenvalue, $E$ (here we measure energy from the gap center). Then $U(r)$ is determined from the condition that $\int dr U^2(r)$ is minimal. This restriction is conventionally incorporated by adding to $\int dr U^2(r)$ the energy, $E\Psi = \langle \Psi | (\mathcal{H} + U) \Psi \rangle$ with Lagrange multiplier, $\lambda$. Then minimization of

$$\lambda \langle \Psi | (\mathcal{H} + U) | \Psi \rangle - \int dr U^2(r) \quad (29)$$

with respect to $U$ yields $U = -\frac{1}{2} |\Psi|^2$.

At this point the following remark is in order. Conventionally, upon substituting the found $U(r)$ back into the Schrödinger equation, the sign of $\lambda$ is chosen from the condition that potential $U(r)$ is attractive. However, in our case of two symmetric bands, Fig. 1, the potential which is attractive for electrons, is repulsive for holes, and vice versa. It turns out that choosing $\lambda = 2$ corresponds to $\nu(E)$ which falls off from $E = V/2$ all the way down to $E = -V/2$. Correspondingly, choosing $\lambda = -2$ leads to the tail $\nu(-E)$ which grows from $E = -V/2$ towards the bottom of conduction band $E = V/2$. Therefore, at $E = 0$, we have two different solutions, with $U(r)$ and $-U(r)$, for which the "electron" and "hole" components of eigenfunction $\Psi$ are related as $(\psi_e, \psi_h) \leftrightarrow (-\psi_h^*, \psi_e^*)$. Thus, in view of exponential character of $\nu(E)$, it is sufficient to set $\lambda = 2$ and consider only positive energies, $E > 0$. The nonlinear instanton equation reads

$$-\frac{V}{2} \psi_e - \frac{\epsilon^2}{\lambda \, t^2_\perp} (\partial_x + i \partial_y)^2 \psi_h - \psi_e \left( |\psi_e|^2 + |\psi_h|^2 \right) = E \psi_e;$$

$$-\frac{V}{2} \psi_h - \frac{\epsilon^2}{\lambda \, t^2_\perp} (\partial_x - i \partial_y)^2 \psi_e - \psi_h \left( |\psi_e|^2 + |\psi_h|^2 \right) = E \psi_h. \quad (30)$$

Then, with exponential accuracy, we have $\nu(E) \propto \mathcal{P} \{ U(r) \}$, where

$$\mathcal{P} \{ U(r) \} = \exp \left[ -\frac{1}{2 \gamma} \int dr U^2(r) \right] \quad (31)$$

is the probability of realization of $U(r)$.

Consider first the energies close to the bottom of conduction band, $-\epsilon = (\frac{V}{2} - E) \ll V$. In this limit, the second equation in the system Eq. (30) can be simplified as

$$\psi_h = -\frac{e}{V \lambda} (\partial_x - i \partial_y)^2 \psi_e. \quad (32)$$

Substituting Eq. (32) into the first equation Eq. (30), and performing rescaling

$$r = c(\lambda t^2_\perp |\epsilon|)^{-1/4} \rho, \quad \psi_e = |\epsilon/\lambda|^{1/2} f(\rho), \quad (33)$$

we arrive to the following dimensionless instanton equation

$$\Delta^2 f(\rho) + f(\rho) - f(\rho)^3 = 0, \quad (34)$$

while the expression for $\nu(\epsilon)$ takes the form

$$\nu(\epsilon) \propto \exp \left[ -\frac{I_4}{2} \frac{\epsilon}{\epsilon_t} \frac{3/2}{\epsilon_t} \right], \quad (35)$$

where $\epsilon_t$ is defined by Eq. (15) and $I_4 = \int d\rho f^4(\rho)$.

Eq. (30) has solutions for arbitrary angular momentum, $M$. However, leading contribution to the density of states comes from azimuthally symmetric solution, $f(\rho)$. Then the hole component Eq. (32) of the wave function corresponds to the momentum $M = 2$, namely

$$\psi_h = \frac{\epsilon}{\sqrt{V \lambda}} e^{-2i\phi} \left( \partial^2_{\rho} - \frac{1}{\rho} \partial_\rho \right) f(\rho). \quad (36)$$

A peculiar feature of the non-linear equation Eq. (34) is that it contains $\Delta^2_\rho$ instead of a usual Laplace operator, $\Delta$. This is a direct consequence of the dispersion
The resulting function Eq. (36) is non-singular at $1_\rho$.

This combination has a well-pronounced minimum at $C_{\text{C}}$ with respect to $E$ for $E = 0$. For $E = 0$, it is reasonable to adopt $s = 2$, which is essentially valid down to the gap center. The result Eq. (35) applies for $\epsilon \ll \epsilon$. We solve Eq. (35) by employing the variational approach on the class of trial functions $f(\rho) = C \exp[-(\rho/\rho_0)^s]$. Minimization of the corresponding functional

$$
\Phi\{f\} = \int d\rho \left[ (\Delta_\rho f)^2 + f^2 - \frac{1}{2}f^4 \right]
$$

with respect to $C$ and $\rho_0$ can be easily performed analytically. The resulting $s$-dependence of $\Phi\{f\}$ has the form

$$
\phi(s) = \left[ \frac{s(s-1) + 2}{2^{3-4/s}} \frac{(1-2/s)}{\sin \pi(1-2/s)} \right]^{1/2}.
$$

This combination has a well-pronounced minimum at $s \approx 1.963$ see Fig. 3. On the other hand, the "hole" wave function Eq. (39) is non-singular at $\rho \to 0$ if $s \geq 2$. Thus it is reasonable to adopt $s = 2$, yielding $C = 1.63$ and $\rho_0 = 2.21$. This allows to specify the numerical factor in the exponent of density of states in Eq. (35), namely $I_4 = 27.36$.

The result Eq. (35) applies for $\epsilon_\ell \ll \epsilon \ll V$. A relevant question for inelastic transport is the density of states at the gap center. For qualitative estimate it is sufficient to substitute $\epsilon = -V/2$ into the Eq. (35), which converges at large $\epsilon$ for $\nu(\epsilon) \propto \epsilon^{-1/4}$. Our main result Eq. (35) applies in the limit of strong disorder when $\gamma > c^2(V/t_L)^4$. On the other hand, we assumed that the gap is not washed out completely by the disorder. Then the upper limit on $\gamma$ can be found by setting $\epsilon = V/2$

V. CONCLUDING REMARKS

1. Prefactor. Eq. (35) describes the tail of the density of states with exponential accuracy. To restore the dimensionality, it is natural to multiply Eq. (35) by $\nu_0(\epsilon_\ell)$, since the smearing of the band-edge is $\sim \epsilon_\ell$. However, since Eq. (35) describes the deep tail, the prefactor contains an additional power of a dimensionless ratio $(|\epsilon|/\epsilon_\ell)$. To establish this power, one has to follow the procedure of calculating the prefactor in the functional integral(33,34). Within this procedure, the origin of a prefactor is the fact that the center of the instanton can be shifted in the plane along both axes. This shifts correspond to the so-called zero modes. Each zero mode contributes a factor $(|\epsilon|/\epsilon_\ell)^{1/4}$. The power $1/4$ reflects the size of the instanton fluctuation, $r_\ell \propto |\epsilon|^{-1/4}$, see Eq. (27). Overall, within a numerical coefficient, the final expression for the density of states in the tail reads

$$
\nu(\epsilon) = \frac{V_1^{1/2} \pi}{c^2 \epsilon_\ell} |\epsilon|^{1/2} \exp\left( -11.6 \frac{|\epsilon|}{\epsilon_\ell}^{3/2} \right).
$$

Note that, unlike the case of parabolic spectrum(32), for $\epsilon(p) \propto p^4$, the prefactor does not diverge. This is because the second-order shift of the band-edge $\sim \gamma \int d\nu_0(\epsilon)/\epsilon$ converges at large $\epsilon$ for $\nu_0(\epsilon) \propto \epsilon^{-1/2}$.

2. Relation to the scattering time. Short-range disorder is characterized by a single parameter, $\gamma$. For comparison with experiment, this parameter can be related to electron scattering time, $\tau_\ell$, in the case when the gate voltage places the Fermi level, $E_F$, well above the smearing, $\epsilon_\ell$, of the band-edge. Expressing $\gamma$ from Eq. (13), and substituting into Eq. (15), we obtain

$$
\epsilon_\ell = \left( \frac{4\pi^2 E_F}{\tau_\ell^2} \right)^{1/3} = \left( \frac{4\pi^2 \eta_\ell^2 c^4}{V^2 \tau_\ell^2} \right)^{1/3}.
$$

In the second identity we had expressed $E_F$ via electron density, $n_\ell$.

3. The role of intervalley scattering. Our assumption that disorder is short-ranged requires that the radius of the impurity potential, $w(r)$, is smaller than the wavelength of electron with energy $\sim V$, which is $\sim c/(V_L)^{1/2}$. This length is much larger than the lattice constant, and we neglected the intervalley scattering. If the radius of $w(r)$ is comparable to the lattice constant, the intervalley scattering becomes as efficient as intravalley scattering. This would not only lift the valley degeneracy of the fluctuation states but also result in their azimuthal asymmetry, much like in the case of degenerate valence band considered in Ref. 33. The consequence of this asymmetry is the change of the numerical factor in the exponent of Eq. (35).

4. Dependence on impurity concentration. Our main result Eq. (35) applies in the limit of strong disorder when $\gamma > c^2(V/2)^4$. On the other hand, we assumed that the gap is not washed out completely by the disorder. Then the upper limit on $\gamma$ can be found by setting $\epsilon = V/2$
in Eq. (39) equating the exponent to 1. Finally, it is convenient to present the domain of validity of Eq. (39) as
\[
\left(\frac{V}{t_L}\right)^4 < \frac{\gamma}{\epsilon^2} < 4.1 \frac{V}{t_L}.
\]
(41)

It follows from the second condition that the minimal \( V = V_c \), at which the gap effectively opens, is proportional to the impurity concentration, as it was stated in the Introduction. We can also rewrite the above condition in terms of dimensionless conductance when the Fermi level is in the conduction band
\[
E_p \tau_p > 1.5 \left(\frac{E_F}{V}\right)^{3/2}.
\]
(42)

Finally, we address the case of low impurity concentration when the first condition Eq. (11) is violated.

An isolated impurity with potential, \( w(r) \), creates a localized state with binding energy \( \epsilon_b = 2\pi^2 mp_0^2 \left( \int drw(r) J_0^2 (p_0r) \right)^2 \). (43)

For the short-range potential, \( w(r) \), the Bessel function in the integrand can be set to 1. Substituting \( p_0 \) and \( m \) from Eqs. (9) and (11), we obtain
\[
\epsilon_b = \frac{\pi^2 Vr_1^2}{4c^2} \left( \int drw(r) \right)^2.
\]
(44)

We see that, for bilayer graphene, the binding energy is proportional to the gap \( \Delta \). The wave function of this localized state not only falls off exponentially with distance, \( r \), from the impurity, but also oscillates as \( J_0(p_0r) \). It is clear that when the average distance between the impurities \( \sim n_i^{-1/2} \) becomes smaller than \( p_0^{-1} \) the impurity band merges with the conduction (valence) band. Remarkably, the criterion
\[
n_i > p_0^2
\]
(45)

also follows from a very different reasoning. The expression Eq. (23) for the tail energy, \( \tilde{\epsilon}_t \), in the weak-disorder regime can be rewritten as
\[
\tilde{\epsilon}_t = \frac{4n_i t_L^2}{c^2} \left( \int drw(r) \right)^2.
\]
(46)

Comparing Eq. (45) to Eq. (39), we find that the ratio \( \tilde{\epsilon}_t/\epsilon_b \) is \( \sim n_i/p_0^2 \). Thus the condition Eq. (45) that neighboring localized states overlap ensures that the impurity band transforms into the tail of the conduction (valence) band. Note also, that in treating the weak-disorder regime we assumed that the correlator of the disorder potential is given by Eq. (1). By making this assumption we already implied that disorder is not due to individual impurities but rather due to fluctuations of impurity concentration, i.e., that the levels Eq. (13) are not formed at \( n_i \) satisfying the condition Eq. (45). In conclusion, we rewrite for completeness the condition of strong disorder in terms of impurity concentration and binding energy of an individual impurity
\[
\frac{V^3}{\epsilon_b t_L^2} < \frac{n_i}{\pi^2 p_0^2} < 4.1 \frac{t_L}{\epsilon_b}.
\]
(47)

We see that the smaller is the gap, the broader is the interval Eq. (47).

VI. ACKNOWLEDGEMENT

We are grateful to A. K. Savchenko for initiating this work. The work was supported by the Petroleum Research Fund under Grant No. 43966-AC10.

APPENDIX A

Similar to Eq. (31), \( \nu(\epsilon) \) in the tail is given by
\[
\nu(\epsilon) \propto \exp \left( -\frac{1}{2\gamma} \int dr |\varphi(r)|^4 \right),
\]
(41)

where the two-component function \( \varphi(r) \) satisfies the equation
\[
\hat{H} \varphi(r) - |\varphi(r)|^2 \varphi(r) = \epsilon \varphi(r),
\]
(42)

with \( \hat{H} \) being the free Hamiltonian with the spectrum Eq. (12) and the eigenfunctions Eq. (13). Searching the solution in the form
\[
\varphi(r) = \int dp B(p) \chi_p^+(r),
\]
(43)

we arrive to the following integral equation for \( B(p) \):
\[
B(p)[\epsilon^+(p) - \epsilon] = \frac{1}{(2\pi)^2} \int drr \left( \prod_{i=1,2,3} dp_i B(p_i) \right) \times \left( \chi_p^{+*} \chi_p^+ \right) \left( \chi_p^{+*} \chi_{p_2} \chi_{p_3} \right).
\]
(44)

Assuming that \( B(p) \) depends only on the absolute value of \( p \), we easily perform the angular integration in (A4). Using explicit forms of the wave function scalar products, we obtain
\[
B(p)[\epsilon^+(p) - \epsilon] = \pi^2 \int dr r \left( \prod_{i=1,2,3} dp_i B(p_i) \right) \times J_2(pr) J_2(p_1r) J_2(p_2r) J_2(p_3r),
\]
(45)

where \( J_2(x) \) is the Bessel function of the second order. The product of \( J_2(p_i r) \) manifests the difference of Eq. (A5) from the corresponding equation in Ref. 28.
The principal step in solving Eq. (A5) is setting all momenta in the right hand side equal to $p_0$. Then the integral over $r$ yields $\frac{1}{2} \ln(\epsilon_m/|\epsilon|)$ so that Eq. (A5) reduces to

$$B(p)\left[\frac{(p-p_0)^2}{2m} - \epsilon\right] = 2p_0 \ln\left(\frac{\epsilon_m}{|\epsilon|}\right) \left[\int_0^\infty dp' B(p')\right]^3.$$  \hspace{1cm} (A6)

This equation has an obvious solution of the form

$$B(p) = \frac{\beta}{(p-p_0)^2/2m + |\epsilon|}.$$  \hspace{1cm} (A7)

Substituting Eq. (A7) into Eqs. (A6) and (A3), we find for constant $\beta$ the value

$$\beta = \frac{1}{2^{1/2} \pi^{1/2} p_0^{-1/2}} \left(\frac{2m}{|\epsilon|}\right)^{-3/4} \ln^{-1/2}(\epsilon_m/|\epsilon|),$$  \hspace{1cm} (A8)

and for $\varphi(r)$ the form

$$\varphi(r) = 2\pi^2 \beta p_0 \left(\frac{m}{|\epsilon|}\right)^{1/2} \left(\frac{J_2(p_0r)}{0}\right),$$  \hspace{1cm} (A9)

which is valid for $r \lesssim (2m|\epsilon|)^{-1/2}$. Finally, Eq. (25) emerges upon substituting Eq. (A9) into Eq. (A1).
