We present Monte Carlo simulations of both the Sivers and the Boer-Mulders effects in the polarized Drell-Yan $\pi^+p^+ \rightarrow \mu^+\mu^-X$ process at the center-of-mass energy $\sqrt{s} \sim 14$ GeV reachable at COMPASS with pion beams of energy 100 GeV. For the Sivers effect, we adopt two different parametrizations for the Sivers function to explore the statistical accuracy required to extract unambiguous information on this parton density. In particular, we verify the possibility of checking its predicted sign change between Semi-Inclusive Deep-Inelastic Scattering (SIDIS) and Drell-Yan processes, a crucial test of nonperturbative QCD. For the Boer-Mulders effect, because of the lack of parametrizations we can make only guesses. The goal is to explore the possibility of extracting information on the transversity distribution, the missing piece necessary to complete the knowledge of the nucleon spin structure at leading twist, and the Boer-Mulders function, which is related to the long-standing problem of the violation of the Lam-Tung sum rule in the unpolarized Drell-Yan cross section.

I. INTRODUCTION

The recent measurement of Single-Spin Asymmetries (SSA) in semi-inclusive $lp^+ \rightarrow h^+X$ Deep-Inelastic Scattering (SIDIS) on transversely polarized hadronic targets $^1$$^2$$^3$$^4$, has renewed the interest in the problem of describing the spin structure of hadrons within Quantum Chromo-Dynamics (QCD) $^5$, and has stimulated since then a large production of phenomenological and theoretical papers. Experimental evidence of large SSA in hadron-hadron collisions was well known since many years $^6$$^7$, but it has never been consistently explained in the context of perturbative QCD in the collinear massless approximation $^8$. The idea of going beyond the collinear approximation opened new perspectives about the possibility of explaining these SSA in terms of intrinsic transverse motion of partons inside hadrons, and of correlations between such intrinsic transverse momenta and transverse spin degrees of freedom. The most popular examples are the Sivers $^9$ and the Collins $^{10}$ effects. In the former case, an asymmetric azimuthal distribution of detected hadrons (with respect to the normal to the production plane) is obtained from the nonperturbative correlation $p_T \times P \cdot S_T$, where $p_T$ is the intrinsic transverse momentum of an unpolarized parton inside a target hadron with momentum $P$ and transverse polarization $S_T$. In the latter case, the asymmetry is obtained from the correlation $k \times P_{h_T} \cdot s_T$, where a parton with momentum $k$ and transverse polarization $s_T$ fragments into an unpolarized hadron with transverse momentum $P_{h_T}$. In both cases, the sizes of the effects are represented by new Transverse-Momentum Dependent (TMD) partonic functions, the so-called Sivers and Collins functions, respectively.

However, SSA data in hadronic collisions have been collected so far typically for semi-inclusive $pp(\uparrow) \rightarrow h(\uparrow)X$ processes, where the factorization proof is complicated by higher-twist correlators $^{11}$ and the power-suppressed asymmetry can be produced by several (overlapping) mechanisms. On the contrary, the theoretical situation of the SIDIS measurements is more transparent. On the basis of a suitable factorization theorem $^{12}$ $^{13}$, the cross section at leading twist contains convolutions involving separately the Sivers and Collins functions with different azimuthal dependences, $\sin(\phi - \phi_S)$ and $\sin(\phi + \phi_S)$, respectively, where $\phi, \phi_S$, are the azimuthal angles of the produced hadron and of the target polarization with respect to the axis defined by the virtual photon $^{14}$. According to the extracted azimuthal dependence, the measured SSA can then be clearly related to one effect or the other $^1$$^2$.

Similarly, in the Drell-Yan process $H_1H_2^\uparrow \rightarrow l^+l^-X$ the cross section displays at leading twist two terms weighted by

sin(\phi - \phi_S) and sin(\phi + \phi_S), where now \phi, \phi_S, are the azimuthal orientations of the final lepton plane and of the hadron polarization with respect to the reaction plane \( \perp \). Adopting the notations recommended in Ref. [16], the first one involves the convolution of the Sivers function \( f_{1T}^1 \) with the standard unpolarized parton distribution \( f_1 \). The second one involves the transversity distribution \( h_1 \) and the Boer-Mulders function \( h_T^1 \), a TMD distribution which is most likely responsible for the violation of the Lam-Tung sum rule in the corresponding anomalous \( \cos 2\phi \) asymmetry of the unpolarized Drell-Yan cross section \[15\]. Hence, a simultaneous measurement of unpolarized and single-polarized Drell-Yan cross sections would allow to extract all the unknowns from data \[17, 18\]. Both the unpolarized Drell-Yan cross section \[15\]. Hence, a simultaneous measurement of unpolarized and single-polarized Drell-Yan SSA for the \( pp^\pm \rightarrow \mu^+\mu^-X \) \[21\] and \( \bar{p}p^\mp \rightarrow \mu^+\mu^-X \) \[17\] processes. With proton beams, we considered collisions at \( \sqrt{s} = 200 \text{ GeV} \) in the kinematic conditions for the foreseen upgrade of RHIC (RHIC II). Even if in \( pp \) collisions the nonvanence partonic contribution to the elementary annihilation is unavoidable (leading, in principle, to lower counting rates), still the kinematics selects a portion of phase space that emphasizes this contribution. The net result is that with a reasonable sample of Drell-Yan events the statistical accuracy allows to unambiguously extract the Sivers function from the corresponding \( \sin(\phi - \phi_S) \) asymmetry, as well as to clearly test its predicted sign change with respect to the SIDIS asymmetry \[21\]. In \( \bar{p}p \) collisions, the cross section is dominated by the valence contribution to the annihilation of a parton (from \( p \)) and an antiparton (from \( \bar{p} \)); hence, in general it is not suppressed as in the previous case (for a quantitative check in our Monte Carlo, see Sec. IVB of Ref. \[21\]). In Ref. \[17\], we selected antiproton beams of 15 GeV, as they could be produced at the High Energy Storage Ring (HESR) at GSI \[22, 23\], and we simulated collisions at \( \sqrt{s} \sim 14 \text{ GeV} \) in the called asymmetric collider mode. The goal was to explore the minimal conditions required for an unambiguous extraction of \( h_1 \) and \( h_T^1 \) from a combined analysis of the \( \sin(\phi + \phi_S) \) and \( \cos 2\phi \) asymmetries in the full (unpolarized + polarized) cross section.

Here, we will reconsider the same scenarios but for the \( \pi^\pm p^l \rightarrow \mu^+\mu^-X \) process at the same \( \sqrt{s} \sim 14 \text{ GeV} \) that can be reached at COMPASS with pion beams of energy 100 GeV. As for \( \bar{p} \) beams, the elementary mechanism is dominated by the annihilation between valence partons (from \( p \)) and valence antipartons (from \( \pi \)). Indeed, a large Sivers effect was predicted in this context by using the same Sivers function fitted to the measured \( \sin(\phi - \phi_S) \) asymmetry in SIDIS \[21\]. Taking advantage on the high statistics reachable with pions, in our Monte Carlo we simulate both \( \sin(\phi + \phi_S) \) SSA in the Drell-Yan cross section. For the Sivers effect we use two parametrizations of \( f_{1T}^1 \): the one of Ref. \[21\], which was deduced by fitting the recent HERMES data for the \( \sin(\phi - \phi_S) \) SSA \[2\]; the one of Ref. \[21\], which is constrained by the recent RHIC data for the \( pp^\pm \rightarrow \pi X \) process at higher energy \[26\]. For the Boer-Mulders effect, since there is no such abundance of data and fits, we follow Ref. \[15\] to constrain \( h_T^1 \) by the azimuthal asymmetry of the corresponding unpolarized Drell-Yan cross section (see also Ref. \[27\] for a similar analysis). Then, we insert, as we did in Ref. \[17\], very different input test functions for \( h_1 \) in order to explore the sensitivity of the simulated SSA within the statistical accuracy.

In Sec. III we review the formalism and the details of the numerical simulation. In Sec. IV we present and discuss our results. Finally, in Sec. IVB we draw some conclusions.

II. GENERAL FRAMEWORK FOR THE NUMERICAL SIMULATION

In a Drell-Yan process, an antilepton-lepton pair with individual momenta \( k_1 \) and \( k_2 \) is produced from the collision of two hadrons with momentum \( P_i \), mass \( M_i \), and spin \( S_i \), with \( i = 1, 2 \). The center-of-mass (c.m.) square energy...
available is $s = (P_1 + P_2)^2$ and the invariant mass of the final lepton pair is given by the time-like momentum transfer $q^2 = M^2 = (k_1 + k_2)^2$. If $M^2, s \to \infty$, while keeping the ratio $0 \leq \tau = M^2 / s \leq 1$ limited, a factorization theorem can be proven ensuring that the elementary mechanism proceeds through the annihilation of a parton and an antiparton with momenta $p_1$ and $p_2$, respectively, into a virtual photon with time-like momentum $q^2$. If $P_1^+$ and $P_2^-$ are the dominant light-cone components of hadron momenta in this regime, then the partons are approximately collinear with the parent hadrons and carry the light-cone momentum fractions $0 \leq x_1 = p_1^+/P_1^+, x_2 = p_2^-/P_2^- \leq 1$, with $q^+ = p_1^+$, $q^- = p_2^-$ by momentum conservation. The transverse components $p_{1T}$ of $p_1$ with respect to the direction defined by $P_i (i = 1, 2)$, are constrained again by the momentum conservation $q_T = p_{1T} + p_{2T}$, where $q_T$ is the transverse momentum of the final lepton pair. If $q_T \neq 0$ the annihilation direction is not known. Hence, it is convenient to select the so-called Collins-Soper frame described in Eq. 4. The final lepton pair is detected in the solid angle $(\theta, \phi)$, where, in particular, $\phi$ (and all other azimuthal angles) is measured in a plane perpendicular to the indicated lepton plane but containing $\hat{h} = q_T / q_T$.

The full expression of the leading-twist differential cross section for the $H_1 H_2^+ \to l^+ l^- X$ process can be written as

$$
\frac{d\sigma}{d\Omega dx_{1}dx_{2}dq_T} = \frac{d\sigma^0}{d\Omega dx_{1}dx_{2}dq_T} + \frac{d\Delta\sigma^1}{d\Omega dx_{1}dx_{2}dq_T} + \frac{\alpha^2}{3Q^2} \sum_f e_f^2 \left\{ A(y) \mathcal{F} \left[ f_1^i (H_1) f_1^j (H_2) \right] + B(y) \cos 2\phi \mathcal{F} \left[ \left( 2 \hat{h} \cdot p_{1T} \hat{h} \cdot p_{2T} - p_{1T} \cdot p_{2T} \right) h_{1T}^+ f_1^i (H_1) h_{1T}^j f_1^j (H_2) \right] \right. 
$$

$$
\left. + \frac{\alpha^2}{3Q^2} |S_{2T}| \sum_f e_f^2 \left\{ A(y) \sin(\phi - \phi_{S_f}) \mathcal{F} \left[ \hat{h} \cdot p_{2T} h_{1T}^+ f_1^i (H_1) h_{1T}^j f_1^j (H_2) \right] \right. \right.
$$

$$
\left. \left. - B(y) \sin(\phi + \phi_{S_f}) \mathcal{F} \left[ \hat{h} \cdot p_{1T} h_{1T}^+ f_1^i (H_1) h_{1T}^j f_1^j (H_2) \right] \right. \right.
$$

$$
\left. \left. - B(y) \sin(3\phi - \phi_{S_f}) \mathcal{F} \left[ \left( 4 \hat{h} \cdot p_{1T} \hat{h} \cdot p_{2T} \right)^2 - 2 \hat{h} \cdot p_{2T} p_{1T} \cdot p_{2T} - \hat{h} \cdot p_{1T} p_{2T}^2 \right) \right. \right.
$$

$$
\left. \left. \times \frac{h_{1T}^+ f_1^i (H_1) h_{1T}^j f_1^j (H_2)}{2M_1^2 M_2^2} \right] \right\}, \tag{1}
$$

where $\alpha$ is the fine structure constant, $d\Omega = \sin \theta d\theta d\phi$, $e_f$ is the charge of the parton with flavor $f$, $\phi_{S_f}$ is the azimuthal angle of the transverse spin of hadron $i$, and

$$
A(y) = \left( \frac{1}{2} - y + y^2 \right) \text{cm} \equiv \frac{1}{4} (1 + \cos^2 \theta) \quad \quad B(y) = y(1 - y) \text{cm} \equiv \frac{1}{4} \sin^2 \theta. \tag{2}
$$

The TMD functions $f_1^i (H), h_{1T}^+ f_1^i (H)$, describe the distributions of unpolarized and transversely polarized partons in an unpolarized hadron $H$, respectively, while $f_{1T}^i (H^\uparrow)$ and the pair $h_{1T}^i f_1^j (H^\downarrow), h_{1T}^j f_1^i (H^\uparrow)$, have a similar interpretation but for transversely polarized hadrons $H^\uparrow$. The convolutions are defined as

$$
\mathcal{F} \left[ DF_1^1 (H_1) DF_2^1 (H_2^\uparrow) \right] = \left\{ dP_{1T} dP_{2T} \delta (P_{1T} + P_{2T} - q_T) \left[ DF_1 (x_1, P_{1T}; f/H_1) DF_2 (x_2, P_{2T}; f/H_2^\uparrow) \right] \right\}. \tag{3}
$$

In previous papers, we made numerical simulations of the SSA generated in Eq. 4 by the azimuthal dependences $\cos 2\phi$ and $\sin (\phi - \phi_{S_f})$ for antiproton beams $H_1 = p$, as well as for double-polarized Drell-Yan processes with $H_1^\uparrow = H_2^\downarrow = p^\uparrow$. A combined measurement of these SSA allows to completely determine the intertwined unknown transversity $h_1$ and Boer-Mulders function $h_{1T}^i$, and the Sivers function $f_{1T}^i$. The Monte Carlo simulation was performed for high-energy proton beams ($\sqrt{s} = 200$ GeV) in the conditions of the foreseen upgrade of RHIC (RHIC II), and for antiproton beams of 15 GeV as they could be produced at HESR-GSI. In the latter case, several scenarios were explored for $5 \lesssim \sqrt{s} \lesssim 14$ GeV and $1.5 < M < 2.5$, $4 < M < 9$ GeV, in order to avoid overlaps with the strange, charm, and bottom quarkonia (where the elementary annihilation does not necessarily proceed through a simple intermediate virtual photon, as it is assumed in Eq. 4). Here, we reconsider the $\sin (\phi - \phi_{S_f})$ and $\sin (\phi + \phi_{S_f})$ asymmetries by using pion beams of 100 GeV as they can be produced at COMPASS, in the fixed target mode such as to reach the same maximum c.m. energy considered at HESR-GSI.
where the complete dependence of the involved TMD parton distributions has been made explicit.

The Monte Carlo events have been generated by the following cross section \[17, 21, 30\]:

\[
\frac{d\sigma}{d\xi dx_1 dx_2 dq_T} = K \frac{1}{s} |\mathcal{T}(q_T, x_1, x_2, M)|^2 \sum_{i=1}^{4} c_i(q_T, x_1, x_2) S_i(\theta, \phi, \phi_{S_2}) ,
\]

where the event distribution is driven by the elementary unpolarized annihilation, whose transition amplitude \(\mathcal{T}\) has been highlighted. In Eq. \(11\), we assume a factorized transverse-momentum dependence in each parton distribution such as to break the convolution \(\mathcal{F}\), leading to

\[
|\mathcal{T}|^2 \approx A(q_T, x_1, x_2, M) F(x_1, x_2) ,
\]

where \(q_T \equiv |q_T|\). The function \(A\) is parametrized and normalized as in Ref. \[31\], where high-energy Drell-Yan \(\pi - p\) collisions were considered. The average transverse momentum turns out to be \(\langle q_T \rangle > 1\) GeV/c (see also the more recent Ref. \[32\]), which effectively reproduces the influence of sizable QCD corrections beyond the parton model picture of Eq. \(10\). The function \(A\) is parametrized and normalized as in Ref. \[31\], where high-energy Drell-Yan \(\pi - p\) collisions were considered. The average transverse momentum turns out to be \(\langle q_T \rangle > 1\) GeV/c (see also the more recent Ref. \[32\]), which effectively reproduces the influence of sizable QCD corrections beyond the parton model picture of Eq. \(10\). It is well known \[33\] that such corrections induce also large \(K\) factors and an \(M\) scale dependence in parton distributions, determining their evolution. As in our previous works \[17, 21, 30\], we conventionally assume in Eq. \(4\) that \(K = 2.5\), but we stress that in an azimuthal asymmetry the corrections to the cross sections in the numerator and in the denominator should compensate each other, as it turns out to actually happen at RHIC c.m. square energies \[34\]. Since the range of \(M\) values here explored is close to the one of Ref. \[31\], where the parametrization of \(A, F, e_i\) in Eq. \(4\) was deduced assuming \(M\)-independent parton distributions, we keep our same previous approach \[17, 21, 30\] and use

\[
F(x_1, x_2) = \frac{\alpha^2}{12Q^2} \sum_f e_f^2 f_1^f(x_1; f/H_1) f_1^f(x_2; f/H_2) + (\bar{f} \leftrightarrow f) ,
\]

where the unpolarized distribution \(f_1^f(x)\) for various flavors \(f = u, d, s\), is taken again from Ref. \[31\].

The whole solid angle \((\theta, \phi)\) of the final lepton pair in the Collins-Soper frame is randomly distributed in each variable. The explicit form for sorting it in the Monte-Carlo is \[17, 21\]

\[
\sum_{i=1}^{4} c_i(q_T, x_1, x_2) S_i(\theta, \phi, \phi_{S_2}) = 1 + \cos^2 \theta + \frac{\nu(x_1, x_2, q_T)}{2} \sin^2 \theta \cos 2\phi
\]

\[
+ |S_{2T}| c_4(q_T, x_1, x_2) S_4(\theta, \phi, \phi_{S_2}) .
\]

If quarks were massless, the virtual photon would be only transversely polarized and the angular dependence would be described by the functions \(c_1 = S_1 = 1\) and \(c_2 = 1, S_2 = \cos^2 \theta\). Violations of such azimuthal symmetry induced by the function \(c_3 \equiv \frac{\nu}{\pi}\) are due to the longitudinal polarization of the virtual photon and to the fact that quarks have an intrinsic transverse momentum distribution, leading to the explicit violation of the so-called Lam-Tung sum rule \[31\]. QCD corrections influence \(\nu\), which in principle depends also on \(M^2\) \[31\]. Azimuthal cos \(2\phi\) asymmetries induced by \(\nu\) were simulated in Ref. \[17\] using the simple parametrization of Ref. \[15\] and testing it against the previous measurement of Ref. \[31\].

If we consider the Sivers effect in Eq. \(11\), the last term in Eq. \(4\) becomes

\[
S_4(\theta, \phi, \phi_{S_2}) = (1 + \cos^2 \theta) \sin(\phi - \phi_{S_2})
\]

and the corresponding coefficient \(c_4\) reads

\[
c_4(q_T, x_1, x_2) = \frac{\sum_f c_f^2 F \left[ \hat{h} \cdot p_{2T} \ f^{f}_1(x_1, p_{1T}) f^{\pm f}_1(x_2, p_{2T}) \right]}{\sum_f c_f^2 F \left[ f^{f}_1(x_1, p_{1T}) f^{f}_1(x_2, p_{2T}) \right]} ,
\]

where the complete dependence of the involved TMD parton distributions has been made explicit.

Viceversa, if we consider the Boer-Mulders effect in Eq. \(11\) the last term in Eq. \(4\) becomes

\[
S_4(\theta, \phi, \phi_{S_2}) = \sin^2 \theta \sin(\phi + \phi_{S_2})
\]
and the corresponding coefficient $c_4$ reads

$$c_4(q_T, x_1, x_2) = -\frac{\sum_f c_f^2 F \left[ \hat{h} \cdot p_{1T} \frac{h_1^{+f}(x_1, p_{1T}) h_1^{f}(x_2, p_{2T})}{M_1} \right]}{\sum_f c_f^2 F \left[ f_1^f(x_1, p_{1T}) f_1^f(x_2, p_{2T}) \right]}. \quad (11)$$

In the following, we will discuss different inputs for the $x$ and $p_T$ dependence of these distributions which allow to calculate the convolutions and determine $c_4$. In any case, following Refs. \[16\] \[21\] \[30\], the general strategy is to divide the event sample in two groups, one for positive values $"U"$ of $S_4$ in Eq. (8) or (10), and another one for negative values $"D"$, then taking the ratio $(U - D)/(U + D)$. Data are accumulated only in the $x_2$ bin, i.e. they are summed upon $x_1$, $\theta$, and $q_T$. Statistical errors for the spin asymmetry $(U - D)/(U + D)$ are obtained by making 10 independent repetitions of the simulation for each individual case, and then calculating for each $x_2$ bin the average asymmetry value and the variance. We checked that 10 repetitions are a reasonable threshold to have stable numbers, since the results do not change significantly when increasing the number of repetitions beyond 6.

### A. The Sivers effect

Recently, the HERMES collaboration released new SSA data for the SIDIS process on transversely polarized protons \[2\], which substantially increase the precision of the previous data set \[1\]. As a consequence, different parametrizations of the Sivers function $f_{1T}^{+f}$ have been extracted from this data set and found compatible also with the recent COMPASS data \[4\] (for a useful comparison among the various approaches see Ref. \[35\]). Following Ref. \[21\], we first simulate the Sivers effect using the parametrization of Ref. \[25\],

$$f_{1T}^{+f}(x, p_T) = -2 N_f \frac{(a_f + b_f) a_f + b_f}{a_f^2 b_f^2} x^{a_f} (1 - x)^{b_f} \frac{M_2 M_0}{p_T^2 + M_0^2} f_1^f(x, p_T) = -2 N_f \frac{1}{\pi \langle p_T^2 \rangle} \frac{(a_f + b_f) a_f + b_f}{a_f^2 b_f^2} x^{a_f} (1 - x)^{b_f} \frac{M_2 M_0}{p_T^2 + M_0^2} e^{-\langle p_T^2 \rangle} f_1^f(x), \quad (12)$$

where $M_2$ is the mass of the polarized proton, $p_T \equiv |p_T|$, and $\langle p_T^2 \rangle = 0.25 \text{ (GeV/c)^2}$ is deduced by assuming a Gaussian ansatz for the $p_T$ dependence of $f_1$ in order to reproduce the azimuthal angular dependence of the SIDIS unpolarized cross section (Cahn effect). Flavor-dependent normalization and parameters in the $x$ dependence are fitted to SIDIS SSA data neglecting the (small) contribution of antiquarks. The resulting parameters $M_0$ and $N_f, a_f, b_f$, with $f = u, d$, are listed in Tab. I. The sometimes poor resolution of the fit forced us to select only the central values in order to produce meaningful numerical simulations.

Following the steps described in Sec. III-1 of Ref. \[21\], in particular the predicted sign change of $f_{1T}^{+f}$ when going from SIDIS to Drell-Yan, we insert the opposite of Eq. (12) into Eq. (11) and simplify it down to

$$c_4 \approx \frac{4M_0 q_T}{q_T^2 + 4M_0^2} \frac{1}{9} \left[ 8 N_u \frac{(a_u + b_u) a_u + b_u}{a_u a_u b_u} x_2^{a_u} (1 - x_2)^{b_u} + N_d \frac{(a_d + b_d) a_d + b_d}{a_d a_d b_d} x_2^{a_u} (1 - x_2)^{b_d} \right]. \quad (13)$$

### TABLE I: Parameters for the Sivers distribution from Ref. \[25\]

| quark up | quark down |
|----------|------------|
| $N_u$    | 0.32 ± 0.11 | $N_d$ | -1.0 ± 0.12 |
| $a_u$    | 0.29 ± 0.35 | $a_d$ | 1.16 ± 0.47 |
| $b_u$    | 0.53 ± 3.58 | $b_d$ | 3.77 ± 2.59 |
| $M_0^2$  | 0.32 ± 0.25 (GeV/c)^2 |

As an alternative choice, we adopt the new parametrization described in Ref. \[21\]. It is inspired to the one of Ref. \[36\], where the transverse momentum of the detected pion in the SIDIS process was assumed to come entirely from the $p_T$ dependence of the Sivers function, and was further integrated out building the fit in terms of specific moments of the function itself. The $x$ dependence of that approach is retained, but a different flavor-dependent
normalization and an explicit $p_T$ dependence are introduced that are bound to the shape of the recent RHIC data on $pp \rightarrow \pi X$ at $\sqrt{s} = 200$ GeV \cite{20}, where large persisting asymmetries are found that could be partly due to the leading-twist Sivers mechanism. The expression adopted is

$$f_{1T}^{\perp f}(x, p_T) = N_f x (1-x) \frac{M_2 p_T^2}{(p_T^2 + \frac{Q^2}{4})^2} f_1^f(x, p_T)$$

$$= N_f x (1-x) \frac{M_2 p_T^2}{(p_T^2 + \frac{Q^2}{4})^2} \frac{1}{\pi \langle p_T^2 \rangle} e^{-p_T^2/\langle p_T^2 \rangle} f_1^f(x),$$

(14)

where $p_0 = 2 \text{ GeV}/c$, and $N_u = - N_d = 0.7$. The sign, positive for $u$ quarks and negative for the $d$ ones, already takes into account the predicted sign change of $f_{1T}^{\perp}$ from Drell-Yan to SIDIS.

Again, following the steps described in Sec. III-2 of Ref. \cite{21}, we can directly insert Eq. (14) into Eq. (9) and get

$$c_4 \approx x_2 \left(1 - x_2\right) \left(\frac{2 p_0 q_T}{q_T^2 + p_0^2}\right)^2 \frac{8 N_u + N_d}{9}.$$  

(15)

The $q_T$ shape is different from Eq. (14) and the peak position is shifted at larger values. This is in agreement with a similar analysis of the azimuthal asymmetry of the unpolarized Drell-Yan data (the violation of the Lam-Tung sum rule \cite{13}). But, more specifically, it is induced by the observed $x_T - q_T$ correlation in the above mentioned RHIC data for $pp \rightarrow \pi X$, when it is assumed that the SSA is entirely due to the Sivers mechanism. This suggests that the maximum asymmetry is reached in the upper valence region such that $x_T \approx x_2 \sim \langle q_T \rangle/5$ \cite{20}.

B. The Boer-Mulders effect

Contrary to the Sivers effect, the lack of data for the Boer-Mulders effect does not allow to build reasonable parametrizations either of $h_1^{\perp f}(x, p_T)$ or of $h_1^f(x, p_T)$. Therefore, similarly to what was done in our previous papers \cite{17, 31}, the strategy of the numerical simulation is based on making guesses for the input $x$ and $p_T$ dependence of the parton distributions, and on trying to determine the minimum number of events required to discriminate various SSA produced by very different input guesses. In fact, this would be equivalent to state that in this case some analytic information on the structure of these TMD parton distributions could be extracted from the SSA measurement.

Following the steps in Sec. IV C of Ref. \cite{17} and in Sec. VI of Ref. \cite{13}, the $p_T$ dependence of the parton distributions is parametrized as

$$f_1^f(x, p_T) = \frac{\alpha_T}{\pi} e^{-\alpha_T p_T^2} f_1^f(x)$$

$$h_1^{\perp f}(x, p_T) = \frac{M_c}{p_T^2 + M_c^2} f_1^f(x, p_T)$$

$$h_1^f(x, p_T) = \frac{\alpha_T}{\pi} e^{-\alpha_T p_T^2} h_1^f(x),$$

(16)

where $\alpha_T = 1 \text{ GeV}^{-2}$ and $M_c = 2.3 \text{ GeV}$. In particular, the $p_T$ dependence of $h_1^{\perp}$ is fitted to the measured $\cos 2\phi$ asymmetry of the corresponding unpolarized Drell-Yan cross section, which is small for $1 \lesssim q_T \lesssim 3 \text{ GeV}/c$ (see, for example, Fig.4 in Ref. \cite{13}). Correspondingly, the $\sin(\phi + \phi_S)$ SSA will turn out to be small for the considered statistically relevant $q_T$ range (see Sec. IIIIB).

Inserting the expressions (16) into Eq. (11), we get

$$c_4 = - \frac{2 M_c q_T}{q_T^2 + 4 M_c^2} \sum_f e_{1f}^2 f_1^f(x_1; f/H_1) h_1^f(x_2; f/H_2) + (f \leftrightarrow f)$$

$$\approx - \frac{2 M_c q_T}{q_T^2 + 4 M_c^2} f_1(x_1; f/H_1) h_1(x_2; f/H_2) = - \frac{2 M_c q_T}{q_T^2 + 4 M_c^2} h_1(x_2; f/H_2)$$

(17)

where the second step is justified by assuming that the contribution of each flavor can be approximated by a corresponding average function \cite{17}.

Two choices with opposite features will be selected for the ratio $h_1(x_2; f/H_2)/f_1(x_2; f/H_2)$, namely the ascending function $\sqrt{x_2}$ and the descending one $\sqrt{1-x_2}$, that both respect the Soffer bound. The goal is to determine
the minimum number of events (compatible with the kinematical setup and cuts) required to produce azimuthal asymmetries that can be clearly distinguished like the corresponding originating distributions. We identify this as the criterion to establish when information on the analytical structure of the involved parton distributions can be extracted from SSA data.

III. RESULTS OF THE MONTE CARLO SIMULATIONS

In this Section, we present results for Monte Carlo simulations of both the Sivers and the Boer-Mulders effects in the Drell-Yan process $\pi^\pm p^\mp \to \mu^\mp \mu^- X$ using input from the previous Sec. II A and II B respectively. The goal is twofold. On one side, to explore the sensitivity of the simulated asymmetry to the different input parametrizations of Eqs. (12) and (14), as well as to directly verify, within the reached statistical accuracy, the predicted sign change of the Sivers function between SIDIS and Drell-Yan (21). On the other side, to make realistic estimates of the minimum number of events required to extract as detailed information as possible on the chiral-odd distributions.

We consider pion beams with energy of 100 GeV hitting a transversely polarized proton target such that $\sqrt{s} \sim 14$ GeV, i.e. the same c.m. energy available at HESR at GSI in the so-called asymmetric collider mode with antiprotons of 15 GeV and protons of 3.3 GeV (17). The transversely polarized proton target is obtained from a $NH_3$ molecule where each $H$ nucleus is fully transversely polarized and the number of “polarized” collisions is 25% of the total number of collisions (17). The muon pair invariant mass is constrained in the range $4 < M < 9$ GeV, in order to avoid overlaps with the resonance regions of the $c\bar{c}$ and $b\bar{b}$ quarkonium systems. At the same time, the theoretical analysis based on the leading-twist cross section (11) should be well established, since higher-twist effects can be classified according to powers of $M_p/M$, $M_p$ is the proton mass.

In the Monte Carlo, the events are sorted according to the cross section (4), supplemented by Eqs. (5) and (6). The asymmetry is simulated by Eq. (7). In particular, for the Sivers effect we use Eqs. (8) and (13) or (15), according to the input parametrization selected for the Sivers function. For the Boer-Mulders effect, we use Eqs. (10) and (17). The events are divided in two groups, one for positive values ($U$) of $\sin(\phi - \phi_{S2})$ in Eq. (8) or of $\sin(\phi + \phi_{S2})$ in Eq. (10), and another one for negative values ($D$), and taking the ratio $(U - D)/(U + D)$. Data are accumulated only in the $x_2$ bins of the polarized proton, i.e. they are summed over in the $x_1$ bins for the pion, in the transverse momentum $q_T$ of the muon pair and in their zenithal orientation $\theta$.

Proper cuts are applied to the $q_T$ distribution according to the different inputs. As for the Sivers effect, the flavor-independent Lorentzian shape in the $p_T$ dependence of Eq. (12) produces a maximum asymmetry for $q_T \sim 1$ GeV/c and a rapid decrease for larger values. Consequently, transverse momenta are selected in the range $0.5 < q_T < 2.5$ GeV/c, because for larger cutoffs the asymmetry is diluted. For the case of Eq. (14), the peak position in $q_T$ is shifted at higher values and the cut is modified as $1 < q_T < 3$ GeV/c. In this way, the ratio between the absolute sizes of the asymmetry and the statistical errors is optimized for each choice, while the resulting $q_T \sim 1.8$ GeV/c is in fair agreement with the one experimentally explored at RHIC (20). As for the Boer-Mulders effect, we keep the latter cut $1 < q_T < 3$ GeV/c. The $\theta$ angular dependence for the Boer-Mulders effect is constrained in the range $60^\circ < \theta < 120^\circ$ due to Eq. (11), because outside these limits the azimuthal asymmetry is too small (17). On the contrary, for the Sivers effect there is no need to introduce cuts because of the $(1 + \cos^2 \theta)$ term in Eq. (8) (21).

We have considered different initial samples. The Sivers mechanism is explored starting from 100 000 events with the $\pi^-$ beam and 25 000 with the $\pi^+$ beam, because the Monte Carlo indicates that the cross section involving $\pi^+$ is statistically disfavoured by approximately the factor $1/4$ (37); in such a way, the two samples can be collected in the same time. As for the Boer-Mulders effect, the lacking of any parametrization makes it impossible to perform an isospin analysis; hence, we used 50 000 events with the $\pi^-$ beam. Statistical errors for $(U - D)/(U + D)$ are obtained by making 10 independent repetitions of the simulation for each individual case, and then calculating for each $x_2$ bin the average asymmetry value and the variance. We checked that 10 repetitions are a reasonable threshold to have stable numbers, since the results do not change significantly when increasing the number of repetitions beyond 6.

A. The Sivers effect

In Fig. 2 the left panel a) displays the sample of 100 000 Drell-Yan events for the $\pi^- p^+ \to \mu^+ \mu^- X$ reaction at $\sqrt{s} \sim 14$ GeV as they are collected in $x_2$ bins for muon invariant mass in the $4 < M < 9$ GeV range. The right panel b) contains 25 000 events for the $\pi^+ p^- \to \mu^+ \mu^- X$ reaction in the same kinematic conditions. Both samples can be accumulated approximately in the same time according to Eq. (13) based on the parametrization (12) of the Sivers function (22); as already discussed, the transverse momentum distribution is constrained in the range $0.5 < q_T < 2.5$ GeV/c. For each bin two groups of events are stored, one corresponding to positive values of $\sin(\phi - \phi_{S2})$ in Eq. (8) (represented by the darker histogram), and one for negative values (superimposed lighter histogram). Since the
FIG. 2: The samples of Drell-Yan events for the Sivers effect in the $\pi^\pm p^\uparrow \rightarrow \mu^\pm \mu^- X$ reaction at $\sqrt{s} \sim 14$ GeV, $4 < M < 9$ GeV, and $0.5 < q_T < 2.5$ GeV/c, using the parametrization of Eq. (12) (see text). a) left panel: 100,000 events with the $\pi^-$ beam; the darker histogram collects events with positive $\sin(\phi - \phi_{S2})$, the superimposed lighter histogram collects the negative ones. b) right panel: the same for 25,000 events with the $\pi^+$ beam.

$\bar{q}q \rightarrow \gamma^*$ mechanism tends to populate the phase space for the lowest possible $\tau$ values [17, 21, 30] compatible with the explored range $0.08 < \tau = x_1 x_2 < 0.4$, this reflects in a $x_1$–integrated distribution which is peaked for $x_2$ values in the valence domain.

FIG. 3: The asymmetry $(U-D)/(U+D)$ corresponding to the histograms of Fig. 2 where $U$ identifies the darker histograms and $D$ the superimposed lighter ones (see text). Triangles for the parametrization of Eq. (12) using the $\pi^-$ beam and with $N_u > 0$; squares for $N_u < 0$. Open triangles using the $\pi^+$ beam and with $N_u > 0$; open squares for $N_u < 0$.

In Fig. 3 the asymmetry $(U-D)/(U+D)$ is shown for each bin $x_2$ between the events of the previous figure accumulated for the positive ($U$) and negative ($D$) values of $\sin(\phi - \phi_{S2})$ in Eq. (5). Average asymmetries and (statistical) error bars are obtained by 10 independent repetitions of the simulation. Boundary values of $x_2$ beyond 0.7 are excluded because of very low statistics. The triangles indicate the results with the $\pi^-$ beam obtained by Eq. (13) assuming that $f_{\perp T}^{\perp}$ changes sign from the parametrization of the SIDIS data to the considered Drell-Yan [20]. For sake of comparison, the squares illustrate the opposite results that one would obtain by ignoring such prediction. Finally, the open triangles and open squares refer to the same situation, respectively, but for the $\pi^+$ beam. The sensitivity of the parameters in Tab. II to the HERMES results for the Sivers effect, reflects in a more important relative weight of the $d$ quark over the $u$ one in the valence $x_2$ range, with opposite signs for the
corresponding normalization $N_f$, $f = u, d$. Consequently, in the valence picture of the $(\pi^-)\pi^+ - p$ collision where the $\bar{u}d$ annihilation dominates, the SSA for the Drell-Yan process induced by $\pi^+$ has opposite sign with respect to $\pi^-$. Moreover, it has an absolute bigger size because the $\bar{d}d$ annihilations are weighted more than the $\bar{u}u$ ones. Apart for very low $x_2$ values where the parton picture leading to Eq. (11) becomes questionable, the error bars are very small and allow for a clean reconstruction of the asymmetry shape and, more importantly, for a conclusive test of the predicted sign change in $f_{1T}^\perp$.

![Diagram](image.png)

**FIG. 4:** The same situation with the same notations as in Fig. 2 but for the parametrization of Eq. (14) with $1 < q_T < 3$ GeV/c (see text).

In Fig. 4 the Drell-Yan events are shown in the same conditions and notations as in Fig. 2 i.e. in the left panel a) 100,000 events for the $\pi^-p^+ \to \mu^+\mu^-X$ reaction at $\sqrt{s} \sim 14$ GeV and for $4 < M < 9$ GeV, and in the right panel b) 25,000 events for the $\pi^+p^+ \to \mu^+\mu^-X$ reaction in the same kinematic conditions. The difference is that the events are now collected according to Eq. (15) based on the parametrization (14) of the Sivers function (21): the cut in the transverse momentum distribution is now $1 < q_T < 3$ GeV/c. Again, the darker histogram refers to events with positive $\sin(\phi - \phi_{S_2})$ in Eq. (8), while the superimposed lighter histogram to the negative ones. Similarly, the density of events is peaked for $x_2$ values in the valence domain because of the dominance of the low $\tau$ portion of the phase space.

![Diagram](image.png)

**FIG. 5:** The same situation with the same notations as in Fig. 3 but for the parametrization of Eq. (14) (see text).

In Fig. 5 the asymmetry $(U - D)/(U + D)$ is shown for each bin $x_2$ between the events of Fig. 4 accumulated for the positive $(U)$ and negative $(D)$ values of $\sin(\phi - \phi_{S_2})$ in Eq. (8). Notations are as in Fig. 3: the triangles indicate
the results with the $\pi^-$ beam obtained by Eq. (15) using a positive normalization $N_u$, which already accounts for the sign change of $f_{1T}^u$ from SIDIS to Drell-Yan; the squares illustrate the results obtained by ignoring such prescription, while the open triangles and open squares refer to the same situation, respectively, but for the $\pi^+$ beam. Again, the opposite normalizations of the two flavors $u, d$ determine the opposite SSA between the $\pi^-$ and the $\pi^+$ beams.

But now in Eq. (14) the relative weight of $u, d$ distributions is the same, hence the absolute sizes of the SSA are approximately the same irrespectively of the charge of the $\pi$ beam. As already anticipated in Sec. II A, the $q_T$ distribution induced by the parametrization (14) is also related to the observed $x_F - q_T$ correlation in the RHIC data for $pp \rightarrow \pi X$ [26], when it is assumed that the SSA is entirely due to the Sivers mechanism. This suggests that the maximum asymmetry is reached in the upper valence region such that $x_F \approx x_2 \sim \langle q_T \rangle / 5 \sim 0.4$ for the considered cut in $q_T$, as it is confirmed in Fig. 5. Similarly to the case of the other parametrization, the statistical error bars are very small and allow for a detailed analysis of the (universality) properties of $f_{1T}^T$. 

B. The Boer-Mulders effect

In Fig. 6 a sample of 50 000 Drell-Yan events for the $\pi^- p^+ \rightarrow \mu^+ \mu^- X$ reaction at $\sqrt{s} \sim 14$ GeV, $4 < M < 9$ GeV, and $1 < q_T < 3$ GeV/c (see text). a) left panel for the choice $h_1(x_2, (f)/H_2^2) / f_1(x_2, (f)/H_2) = \sqrt{1 - x_2}$ (if) represents a common average term that replaces each contribution in the flavor sum, for further details see text); the darker histogram collects events with positive $\sin(\phi + \phi_{S_2})$, the superimposed lighter histogram collects the negative ones. b) right panel: the same for $h_1(x_2, (f)/H_2^2) / f_1(x_2, (f)/H_2) = \sqrt{x_2}$. 

FIG. 6: The sample of 50 000 Drell-Yan events for the Boer-Mulders effect in the $\pi^- p^+ \rightarrow \mu^+ \mu^- X$ reaction at $\sqrt{s} \sim 14$ GeV, $4 < M < 9$ GeV, and $1 < q_T < 3$ GeV/c (see text). a) left panel for the choice $h_1(x_2, (f)/H_2^2) / f_1(x_2, (f)/H_2) = \sqrt{1 - x_2}$ (if) represents a common average term that replaces each contribution in the flavor sum, for further details see text); the darker histogram collects events with positive $\sin(\phi + \phi_{S_2})$, the superimposed lighter histogram collects the negative ones. b) right panel: the same for $h_1(x_2, (f)/H_2^2) / f_1(x_2, (f)/H_2) = \sqrt{x_2}$. 

The error bars represent statistical errors only. As it is evident in the figure, the open triangles describe a SSA which statistically reflects the ascending trend of the input function $\sqrt{x_2}$, while it is not the case for the other choice. Despite the small error bars, which allow to state that both SSA are nonvanishing and to distinguish the two cases in the narrow range $0.1 < x_2 < 0.3$, it is not possible to conclude that specific information on the analytic dependence of $h_1(x)$ can be extracted from such simulation, contrary to what is claimed in Ref. [27]. The reached statistical accuracy indicates that the size of the sample may not be responsible for such failure. Rather, the $p_T$
and the Boer-Mulders

the proton polarization, respectively, with respect to the reaction plane. The first one involves the convolution of the mechanism. In particular, the Monte Carlo was based on the Drell-Yan leading-twist cross section, because higher transverse momentum \( \langle p_T^2 \rangle \) is that the former displays an emphasized relative importance of the unfavoured higher energy \([26]\), when it is assumed that the SSA is driven by the Sivers mechanism only. The main difference parametrizations of SSA in SIDIS \([2]\); the one of Ref. \([21]\), which is constrained by the recent RHIC data for the Drell-Yan cross section \([15]\). The second convolution involves the so-called Sivers function \( \phi \). Lam-Tung sum rule, the long-standing problem of an anomalous \( \cos 2\phi \) asymmetry of the kind \( \sin(\phi + \phi_{SL}) \) asymmetries in single-polarized Drell-Yan processes.

dependence of \( h_1^\perp \) in Eq. \( 16 \) induces the overall small size of the displayed SSA. Moreover, the Soffer bound and the flavor independence of the analysis further reduce the selectivity power of the final Monte Carlo output. In particular, the latter issue calls for specific parametrizations of \( h_1^\perp (x, p_T) \) and \( h_2^\perp f (x, p_T) \), whose unavailability reflects the lacking of experimental data for \( \sin(\phi + \phi_{SL}) \) asymmetries in single-polarized Drell-Yan processes.

IV. CONCLUSIONS

In a series of previous papers \([17, 30]\), we investigated the spin structure of the proton using numerical simulations of single- and double-polarized Drell-Yan Single-Spin Asymmetries (SSA) for the \( \bar{p}\bar{p}^\uparrow \rightarrow \mu^+\mu^- X \) process as well as for the \( pp^\uparrow \rightarrow \mu^+\mu^- X \) one \([21]\). We selected muon pair invariant masses in the range \( 4 < M < 9 \) GeV (and also \( 12 < M < 40 \) GeV for the case of proton beams), where there is no overlap with the resonance regions of the \( cc \) and \( bb \) quarkonium systems and the elementary annihilation can be safely assumed to proceed through the \( q\bar{q} \rightarrow \gamma^* \) mechanism. In particular, the Monte Carlo was based on the Drell-Yan leading-twist cross section, because higher twists may be suppressed as \( M_p/M \), where \( M_p \) is the proton mass.

As for single-polarized reactions, two interesting contributions generate azimuthal asymmetries of the kind \( \sin(\phi + \phi_S) \) and \( \sin(\phi - \phi_S) \), where \( \phi \) and \( \phi_S \) are the azimuthal orientations of the plane containing the final muon pair and of the proton polarization, respectively, with respect to the reaction plane. The first one involves the convolution of the transversity \( h_1 \), the missing piece necessary to complete the knowledge of the nucleon spin structure at leading twist, and the Boer-Mulders \( h_1^\perp \), another chiral-odd parton density which is most likely responsible for the violation of the Lam-Tung sum rule, the long-standing problem of an anomalous \( \cos 2\phi \) asymmetry of the corresponding unpolarized Drell-Yan cross section \([16]\). The second convolution involves the so-called Sivers function \( f_{1T}^\perp \), a "naive T-odd" partonic density that describes how the distribution of unpolarized quarks is distorted by the transverse polarization of the parent hadron. As such, \( f_{1T}^\perp \) contains unsuppressed information on the orbital motion of hidden confined partons and on their spatial distribution inside the proton \([19]\).

In this paper, we have reconsidered the same scenario but for the \( \pi^+ p^\uparrow \rightarrow \mu^+\mu^- X \) process at \( \sqrt{s} \sim 14 \) GeV, that can be reached at COMPASS with pion beams of energy 100 GeV and transversely polarized proton fixed targets. As with antiproton beams, the elementary mechanism is dominated by the annihilation between valence partons (from \( p \) and valence antipartons (from \( \pi \)). Taking advantage on the high statistics reachable with pions, in our Monte Carlo we have simulated both \( \sin(\phi \pm \phi_S) \) SSA in the Drell-Yan cross section. For the Sivers effect we have used two parametrizations of \( f_{1T}^\perp \): the one of Ref. \([24]\), which was deduced by fitting the recent HERMES data for the \( \sin(\phi \pm \phi_S) \) SSA in SIDIS \([2]\), the one of Ref. \([21]\), which is constrained by the recent RHIC data for the \( pp^\uparrow \rightarrow \pi X \) process at higher energy \([26]\), when it is assumed that the SSA is driven by the Sivers mechanism only. The main difference is that the former displays an emphasized relative importance of the unfavoured \( d \) quark, and it gives an average transverse momentum \( \langle q_T \rangle \) of the lepton pair lower than the latter. Consistently, we have built SSA by integrating

\[
\begin{align*}
\text{asymmetry} & = \frac{(U - D)}{(U + D)} \\
\text{vs. } x_2 &
\end{align*}
\]

FIG. 7: The asymmetry \( (U - D)/(U + D) \) corresponding to the histograms of Fig. 6, where \( U \) identifies the darker histograms and \( D \) the superimposed lighter ones (see text). Triangles for \( h_1(x_2, (f)/H_2^z)/f_1(x_2, (f)/H_2) = \sqrt{1 - x_2} \). Open triangles for \( h_1(x_2, (f)/H_2^z)/f_1(x_2, (f)/H_2) = \sqrt{x_2} \).
the $q_T$ distribution with adequate cuts, namely $0.5 < q_T < 2.5$ GeV/$c$ for the former parametrization, and $1 < q_T < 3$ GeV/$c$ for the latter one. Results have been presented as binned in the parton momenta $x_2$ of the polarized proton, i.e. by integrating also upon the antiparton partner momenta $x_1$ and the zenithal muon pair distribution $\theta$ with no further cuts. For the Boer-Mulders effect, since there is no such abundance of data and fits, we have used, as we did in Ref. 16, very different input test functions and we have explored the sensitivity of the simulated $\sin(\phi + \phi_S)$ asymmetry within the reached statistical accuracy, integrating $q_T$ in the range $1 < q_T < 3$ GeV/$c$. Again, results have been presented as binned in $x_2$ by integrating also upon $x_1$ and $\theta$, but with the further constraint $60^\circ < \theta < 120^\circ$ induced by the factor $\sin^2 \theta$ which drives the angular distribution of muon pairs.

Given the very different situations for the two analyses, also the goals are different. For the Sivers effect, the numerical simulation aims to establish the necessary statistical accuracy to distinguish different input parametrizations and to test the (universality) properties of the Sivers function, in particular its predicted sign change when going from SIDIS to the Drell-Yan process 20. As for the Boer-Mulders effect, the goal is to make input guesses and to try to determine the minimum number of events required to discriminate various SSA produced by very different input guesses, that would allow to extract as detailed information as possible on the chiral-odd distributions $h_1^\perp$ and $h_1$.

In all cases, sorted events have been divided in two groups, corresponding to opposite azimuthal orientations of the muon pair with respect to the reaction plane (conventionally indicated with $U$ and $D$), and the asymmetry $(U - D)/(U + D)$ has been considered. Statistical errors have been obtained by making 10 independent repetitions of the simulation for each individual case and, then, calculating for each $x_2$ bin the average asymmetry and the variance. For the Sivers effect, a starting sample of 100,000 events has been selected for the $\pi^-$ beam. Since, from the Monte Carlo, the cross section with $\pi^+$ turns out statistically unfavoured by a factor $1/4$ 21, we have reduced the sample to 25,000 events for the $\pi^+$ beam in order to compare situations with the same "effective luminosity". As for the Boer-Mulders effect, because of the unavailability of fits and isospin analyses, we have used 50,000 events with the $\pi^-$ beam. In all cases, the $1/\tau$ behaviour of the cross section, induced by the $\gamma^*$ propagator, has a twofold effect. It produces the highest density of events for bins in the valence domain, typically for $x_2 \sim 0.3$. At the given $\sqrt{s}$, it also grants that the considered invariant mass range allows to explore the most populated portion of phase space, while avoiding overlaps with ranges where the elementary mechanism could be more complicated and the leading-twist analysis more questionable. The direct consequence is that, with a very large statistics of pions available, very small error bars are reached, except for boundary $x_2$ values.

The availability of different parametrizations of the Sivers function, obtained from independent sets of data, allows for a deep analysis of the flavor dependence of the resulting Drell-Yan SSA, as well as for a test of the universal properties of this parton density. It turns out that the asymmetry always changes sign when switching from the $\pi^-$ to the $\pi^+$ beam, because in the valence picture of the $(\pi^-)\pi^+ - p$ collision the $\bar{u}u \bar{d}d$ annihilation dominates, and both the parametrizations here considered have opposite signs for the $u$ and $d$ valence quarks. The parametrization of Ref. 22, being deduced by SIDIS data for the Sivers effect 2, displays a more important relative weight of the $d$ quark over the $u$, which reflects in a smaller absolute size of the SSA with the $\pi^-$ beam with respect to the $\pi^+$ case. No such evidence is shown by the parametrization of Ref. 21, constrained by data for the $pp^\rightarrow \pi X$ process at $\sqrt{s} = 200$ GeV 24, where also the higher $q_T$ induces a maximum of the asymmetry at higher $x_2$, typically $x_2 \sim 0.4$. In both the considered cases, we have simulated the asymmetry assuming or neglecting the predicted sign change of the Sivers function when replacing the SIDIS with the Drell-Yan process 20. The corresponding results have, of course, opposite signs, but, noticeably, the very small statistical error bars allow to clearly distinguish between one choice or the other extreme. We conclude that with the considered sample of events it is possible to perform such important test of nonperturbative QCD using pion beams and transversely polarized proton targets in the kinematic conditions that can be prepared at COMPASS.

Unfortunately, for the Boer-Mulders effect the lack of data and parametrizations of the involved parton distributions forbids a thorough analysis. The $p_T$ dependence of $h_1^\perp$ is inherited by fitting the measured $\cos 2\phi$ asymmetry of the corresponding unpolarized Drell-Yan cross section: for the statistically relevant range $1 < q_T < 3$ GeV/$c$, the $\sin(\phi + \phi_S)$ asymmetry turns out to be small. We have further approximated the transversity distribution by using a "flavor-averaged" ratio between $h_1(x_2)$ itself and the unpolarized parton distribution $f_1(x_2)$, and we have simulated it by integrating upon $x_1$, $q_T$, $\theta$, and inserting very different input test functions of $x_2$, one ascending and one descending, but all satisfying the general constraints (like the Soffer bound, that puts a strong upper bound on the size of $h_1$). The small statistical errors allow to conclude that the resulting $(U - D)/(U + D)$ asymmetries, though small, are certainly nonvanishing. But the displayed trends in $x_2$ are very similar and do not reflect the very different inputs. Hence, we conclude that in the present stage a measurement of such an asymmetry would not help in extracting information on the transversity $h_1$ and/or the Boer-Mulders function $h_1^\perp$.
