Wind Loads on Single-span Plastic Greenhouses and Solar Greenhouses

Zai Q. Yang¹, Yong X. Li¹,₃, Xiao P. Xue², Chuan R. Huang¹, and Bo Zhang¹

SUMMARY. Wind tunnel tests were conducted in an NH-2-type wind tunnel to investigate the wind pressure coefficients and their distribution on the surfaces of a single-span plastic greenhouse and a solar greenhouse. Wind pressures at various points on the surfaces of the greenhouse models were simultaneously measured for various wind directions. The critical wind speeds, at which damage occurred on the surfaces of single-span plastic greenhouses and solar greenhouses, were derived. To clearly describe the wind pressure distribution on various surface zones of the greenhouses, the end surface and top surface of the plastic greenhouse and the transparent surface of the solar greenhouse were divided into nine zones, which were denoted as Zone I to Zone IX. The results were as follows: 1) At wind direction angles of 0° and 45°, the end surface of the single-span plastic greenhouse was on the windward side, and the maximum positive wind pressure coefficient was near 1. At wind direction angles of 90° and 180°, the entire end surface of the single-span plastic greenhouse was on the leeward side, and the maximum negative wind pressure coefficient was near −1. The maximum positive wind pressure on the end surface of the single-span plastic greenhouse appeared in Zone IV at a wind direction angle of 15°, whereas the maximum negative pressure appeared in Zone VIII at a wind direction angle of 105°. 2) Most of the wind pressure coefficients on the top surface of the plastic greenhouse were negative. The maximum positive and negative wind pressure coefficient on the top surface of the plastic greenhouse occurred in Zones I and II, respectively, at a wind direction angle of 60°. 3) At a wind direction angle of 0°, the distribution of wind pressure coefficient contours was steady in the middle and lower zones of the transparent surface of the solar greenhouse, and the wind pressure coefficients were positive. At a wind direction angle of 90°, the wind pressure coefficients were negative on the transparent surface of the solar greenhouse. A maximum positive wind pressure coefficient was attained at a wind direction angle of 30° in Zone IX, whereas the maximum suction force occurred in Zone VII at a wind direction angle of 135°. 4) The minimum critical wind speeds required to impair the single-span plastic greenhouse and solar greenhouse were 14.5 and 18.9 m s⁻¹, respectively.

facilities were calculated. The results were expected to provide a scientific basis for the optimal design of agricultural facilities and the prevention of windstorm damage.

**Materials and methods**

The tests were conducted in Oct. 2011 in an NH-2-type single-circumfluence low-speed wind tunnel housed at Nanjing University of Aeronautics and Astronautics, Nanjing, China. The wind tunnel was 20 m long, 3 m wide, and 2.5 m high, with a maximum continuously adjustable wind speed of 90 m·s$^{-1}$. An open-country exposure was simulated in the wind tunnel. The mean velocity profile of the flow had a logarithmic law with a roughness length of 0.16 cm. Assuming a boundary layer scale of 1:6, the full-scale value of roughness length was 0.96 cm, which was within the range of full-scale measurements for flat open-country exposure (Tieleman, 2003). The heterogeneity of wind speed was less than 2% in the flow field of the test zone, the turbulence intensity was within a range of 0.10–0.14 at the ridge height of the models and the airstream deflection angles $\Delta\alpha$...
and $\Delta \beta$ were less than 0.5°. The axial static pressure gradient was less than 0.004 Pa·m$^{-1}$.

The models were made based on typical types of single-span plastic greenhouses and solar greenhouses in China, with a geometric scale of 1:6 (Fig. 1). The single-span plastic greenhouse model (Fig. 2A) contained a top height of 0.475 m, a shoulder height of 0.250 m, a width of 1.0 m, and a length of 1.155 m; the length of the top curve was one-half of an ellipse in which the semimajor axis was 0.5 m and the semiminor axis was 0.225 m. The solar greenhouse model (Fig. 2B) contained a span of 1.21 m, a ridge height of 0.45 m, a back wall height of 0.3 m, a back slope horizontal projection of 0.26 m, and a length of 1.10 m; the length of the top curve was one-fourth of an ellipse in which the semimajor axis was 0.95 m and the semiminor axis was 0.45 m. The blockage ratios of the plastic greenhouse model and solar greenhouse model were 4.7% and 3.9%, respectively, which did not exceed 5% of the wind tunnel cross section and was regarded as acceptable (Biagini et al., 2007).

The surfaces of the single-span plastic greenhouse were divided into the end surface and the top surface, and the top surface comprised the roof surface, the left side and the right side. For the solar greenhouse, only the transparent surface was studied because the nontransparent parts (sidewall, back wall, and back slope) of the solar greenhouse were made from brick, cement, and adobe and were much more difficult to be damaged than the transparent part. The test point arrangements for the end surface and the top surface of the single-span plastic greenhouse model were shown in Fig. 1A and B, respectively. Three rows of test points, which were denoted as A1, A2, and A3 and comprised a total of 63 test points, were arranged on the end surface. Test points 1 to 21 were uniformly distributed on each row with an interval of 47.5 mm. In row A3, each test point was located 10 mm from the top arc. Three rows of test points, which were denoted as A4, A5, and A6 and comprised a total of 129 test points, were arranged on the top surface of the single-span plastic greenhouse model. Test points 1 to 43 were uniformly arranged on each row with an interval of 38.67 mm.

Fig. 3. Distribution of wind pressure coefficients on the end surface of the single-span plastic greenhouse at different wind direction angles (A, B, C, and D denote wind direction angle of 0°, 45°, 90°, and 180°, respectively).

Fig. 4. Distribution of wind pressure coefficients on the top surface of the single-span plastic greenhouse at different wind direction angles (A, B, C, and D denote wind direction angle of 0°, 45°, 90°, and 180°, respectively).
A total of 145 test points, which were denoted by A1, A2, A3, A4, and A5 as shown in Fig. 1C, were arranged on the transparent surface of the solar greenhouse model with an interval of 276.25 mm between the rows. For each row, test points 1 to 29 were uniformly distributed with an interval of 41.86 mm. To effectively analyze the wind pressure distribution on various surface zones of the greenhouse, the end surface and top surface of the plastic greenhouse model and the transparent surface of the solar greenhouse model were divided into nine zones, which were denoted with Zone I to Zone IX (Fig. 1). The test models, which were fixed on the turntable of the wind tunnel, turned to form different wind direction angles between the wind and the model. Due to the symmetry of the model, a total of 13 wind direction angles from 0° to 180° were tested with an interval of 15° and a test wind speed of 20 m·s⁻¹.

The wind pressure distribution on the model surface is typically expressed as a wind pressure coefficient, which is a dimensionless definite value and does not vary with wind speed. The wind pressure coefficient can be calculated as (Gu et al., 2010; Xie et al., 2001)

\[ CP_i = \frac{P_i - P_0}{P_0 - P_\infty} \]  

where \( CP_i \) is the wind pressure coefficient (dimensionless) at the \( i \) measuring point of the model, \( P_i \) is the static pressure (Pascal) at the \( i \) measuring point of the model, \( P_\infty \) is the static pressure (Pascal) at the reference point, and \( P_0 \) is the total pressure (Pascal) at the reference point. A wind pressure coefficient greater than zero signifies positive pressure and less than zero signifies negative pressure.

In addition to Eq. [1], the wind pressure coefficient can also be calculated according to the following equation (Gu et al., 2010; Xie et al., 2001):

\[ CP_i = \frac{W_i}{W} \]  

where \( W_i \) is the actual pressure (Newtons) at the \( i \) measuring point and \( W \) is the inflow dynamic pressure (Newtons) at the same measuring point. According to the Bernoulli equation, the inflow dynamic pressure can be expressed as (Gloria et al., 2005; Tamura et al., 2001)

\[ W = \frac{1}{2} \rho v^2 \]  

where \( \rho \) is the air density (1.25 kg·m⁻³) and \( v \) is the wind speed (meters per second). By inserting Eq. [3] into Eq. [2], the actual pressure (Newtons) at the \( i \) measuring point can be calculated as

\[ W_i = 0.625 CP_i v^2 \]  

According to the General Administration of Quality Supervision, Inspection and Quarantine of the People’s Republic of China (2002), the maximum load for single-span plastic greenhouses and solar greenhouses are 196 and 313.6 N·m⁻², respectively. Based on Eq. [4], the critical wind speed can be calculated for various zones on surfaces of facilities at different wind direction angles.

The wind pressure contours were created using Suffer 11.

**Results and discussion**

The contours that depict the distribution of wind pressure coefficients on the end surface of the single-span plastic greenhouse at different wind direction angles were shown in Fig. 3. At wind direction angles of 0° and 45° (Fig. 3A and B), the end surface of the plastic greenhouse was on the windward side. The contours at the edge of the windward zones were dense, which indicated a dramatic change in wind pressure coefficients, and the maximum positive wind pressure coefficient was \( \approx 1 \). At wind direction angles of 90° and 180° (Fig. 3C and D), the end surface of the plastic greenhouse was on the leeward zone, where the contour distribution of the wind pressure coefficients were relatively sparse and the maximum negative wind pressure coefficient was near zero.

The contours that represent the distribution of the wind pressure coefficients on the top surface of the single-span plastic greenhouse at different wind direction angles are shown in Fig. 4. At wind direction angles of 0° and 180° (Fig. 4A and D), the top surface of the plastic greenhouse was in the leeward zone, where all wind pressure coefficients were negative and the contour distribution was uniform; these results indicated a smooth variation in wind pressure. When the wind direction angles were 45° and 90° (Fig. 4B and C), the wind pressure coefficients were positive in the windward zones on the top surface of the single-span plastic...
greenhouse. High negative pressure zones appeared at the edge of the windward zone and the roof ridge of the single-span plastic greenhouse, with significant variation in the gradients of the wind pressure coefficients.

In Fig. 5, the contours of the distribution of the wind pressure coefficients on the transparent surface of the solar greenhouse were depicted for different wind direction angles. The figure demonstrated that at a wind direction angle of 0° (Fig. 5A), the front zone of the transparent surface of the solar greenhouse was in the windward zone, the wind pressure coefficients were all positive and the contours of the distributions were uniform. The variation in wind pressure coefficients was smooth in the rear zones of the transparent surface of the solar greenhouse, and the wind pressure coefficients were negative. At a wind direction angle of 45° (Fig. 5B), the wind pressure coefficients were positive on the windward side of the transparent surface of the solar greenhouse. A high negative pressure zone formed at the junction site of the back slope and the transparent surface, and a large variation in the gradient of wind pressure coefficient, which was related to the flow separation of wind, was evident. At a wind direction angle of 90° (Fig. 5C), the wind pressure coefficients on the top surface of the solar greenhouse were negative because the airflow was blocked by the back slope and back wall. When the wind direction angle was 180° (Fig. 5D), the airflow passed through the side wall and the wind pressure coefficients on the transparent surface of the solar greenhouse were negative.

The average value of wind pressure coefficients for all test points in each zone represented the average wind pressure coefficient within the zone. Figure 6A displayed the variation in wind pressure coefficients for various zones on the end surface of the single-span plastic greenhouse. When the wind direction angle changed from 0° to 180°, the wind pressure coefficients in the nine zones exhibited a consistent trend, which ranged from positive to negative values. After reaching a maximum negative pressure, the suction force gradually weakened to zero at a wind direction angle of 180°. As the wind direction angle was rotated above 90°, the end surface of the plastic greenhouse changed from windward to leeward, and the wind pressure coefficients in various zones yielded negative values. At a wind direction angle of 135°, the wind pressure coefficients for various zones on the end surface of the plastic greenhouse were similar. When the wind direction angle was 180°, the wind had minimal effect on the end surface of the single-span plastic greenhouse. A maximum positive wind pressure of 0.94 appeared in Zone IV at a wind direction angle of 15°, whereas a maximum negative pressure of −0.84 appeared in the VIII zone at a wind direction angle of 105°. Zone IV was the most easily damaged zone on the end surface of the single-span plastic greenhouse.

When the wind direction angle changed from 0° to 180°, the wind pressure coefficients in Zones I, IV, and VII on the top surface (Fig. 6B) of the single-span plastic greenhouse changed from negative to positive and then from positive to negative, but the wind pressure coefficients in Zones II, III, V, VI, VIII, and IX were always negative. This trend was because rotating the wind direction angle from 0° to 180° caused Zones I, IV, and VII to appear on the windward side in sequence; however, Zones II, III, V, VI, VIII, and IX were always present on the leeward side during this process. Due to the symmetry of the single-span plastic greenhouse, the variations in wind pressure coefficients exhibited opposite trends with increases in wind direction angles between Zones I and VII, Zones II and VIII, and Zones III
and IX, respectively. The maximum positive wind pressure coefficient was near 0.5, which occurred in Zone I when the wind direction angle was 60°. The maximum suction appeared at a wind direction angle of 60° in Zone II, where the wind pressure coefficient was near –1.5. Zone II was the most easily damaged zone on the top surface of the single-span plastic greenhouse.

When the wind direction angle changed from 0° to 180°, the wind pressure coefficients for Zones III, VI, and IX of the transparent surface of the solar greenhouse changed from positive to negative (Fig. 6C), whereas the wind pressure coefficients in Zones I, II, IV, V, VII, and VIII were all negative during the process. As the wind direction angle rotated from 0° to 180°, Zones III, VI, and IX were present on the windward side and Zones I, II, IV, V, VII, and VIII were present on the leeward side. The wind pressure coefficients varied slightly with the variation in wind direction angle in Zones III and VI. The maximum positive wind pressure coefficient occurred at a wind direction angle of 30° in Zone IX. The maximum suction force appeared in Zone VII at a wind direction angle of 135°, which was near –1.41. Zone VII was the most easily damaged zone in the solar greenhouse.

Table 1. Maximum wind pressure coefficients and the corresponding critical wind speeds for damage to various zones of single-span plastic greenhouses.

not been validated due to lack of statistical details. Future research will be focused on the correction and validation of minimum critical wind speed for damage to horticultural facilities.

Limited by the experimental facilities, the number of measuring points in the wind tunnel test is always insufficient, which may affect the accuracy of the results. With advances in computer technologies, computational fluid dynamics (CFD) have been used to compensate for insufficient wind tunnel test data (Mistriotis and Briassoulis, 2002). Based on wind tunnel tests, the use of CFD technology can help to accurately obtaining pressure distributions on the surfaces of facilities. Therefore, combining wind tunnel tests with CFD technology to determine pressure distributions on facilities is an important direction for the future study of surface wind load on greenhouses.
