(Dated: March 23, 2022)

We show that the optical absorption spectra of boron nitride (BN) nanotubes are dominated by strongly bound excitons. Our first-principles calculations indicate that the binding energy for the first and dominant excitonic peak depends sensitively on the dimensionality of the system, varying from 0.7 eV in bulk hexagonal BN via 2.1 eV in the single sheet of BN to more than 3 eV in the hypothetical (2, 2) tube. The strongly localized nature of this exciton dictates the fast convergence of its binding energy with increasing tube diameter towards the sheet value. The absolute position of the first excitonic peak is almost independent of the tube radius and system dimensionality. This provides an explanation for the observed “optical gap” constancy for different tubes and bulk hBN [R. Arenal et al., to appear in Phys. Rev. Lett. (2005)].

PACS numbers: 71.35.-y, 61.46.+w, 81.07.De

In complete analogy to carbon nanotubes, boron nitride nanotubes can be thought of as cylinders that are obtained when a single sheet of hexagonal BN is rolled onto itself. Hexagonal BN (hBN) is a large band-gap insulator. Since the band-structure of the tubes can be constructed from the band-structure of the sheet through the zone-folding procedure, the band-gap of BN tubes is similarly large, independently of their radius and chirality. The detailed knowledge of the optical properties of BN tubes is indispensable for their characterization and may help to guide their use as nanoelectronic devices. E.g., BN nanotubes have been used to build a field effect transistor. Furthermore, experiments on ultraviolet luminescence of bulk BN suggest to explore the use of BN nanotubes as ultraviolet light sources. In this context, it is crucial to know about possible excitonic states whose importance has been recently shown for the optical spectra of carbon nanotubes. For the wide band-gap BN tubes, we expect even stronger excitonic effects.

Very recently, two experimental studies of the optical properties of BN nanotubes have appeared in this journal which strongly contradict each other. Both studies compare their spectra to the one of bulk BN which has its first absorption peak at 6.1 eV and an onset of absorption at about 5.8 eV. Lauret et al. have measured two additional peaks in the optical absorption spectra of BN tubes at 4.45 and 5.5 eV. The lower of these two peaks was interpreted as a due to a bound exciton. Arenal et al., on the contrary, have measured the electron-energy loss spectra (EELS) of isolated BN tubes and obtained a constant “optical gap” of 5.8 eV for bulk BN and different single and multi-wall tubes. For a proper interpretation of the spectra, one has to take into account that already the absorption peak of bulk hBN at 6.1 eV is due to a strongly bound Frenkel exciton. The question to be asked is therefore: how does the binding energy of this exciton change as we compare the quasi-two dimensional BN sheet and the quasi-1D BN nanotubes with the 3D bulk BN. Furthermore: Up to which diameter do tubes exhibit one-dimensional excitonic effects? We show in this letter that the excitonic binding energy increases strongly with lower dimensionality. At the same time, however, the quasi-particle gap strongly increases such that the absolute position of the first (excitonic) absorption peak remains almost constant in agreement with the experiments of Ref. 10. Furthermore, we address the role of dark singlet and triplet exciton for ultraviolet luminescence.

So far, the optical properties of BN nanotubes have only been calculated on the level of the random-phase approximation (RPA), i.e., in the picture of independent-particle excitations. In this paper we use the Green’s function approach of many-body perturbation theory to include electron-electron and electron-hole effects. Our calculations of the optical absorption spectra, proceed in three steps. We first calculate the Kohn-Sham wave-functions of the valence band states and a large number of conduction band states using density functional theory (DFT) in the local-density approximation (LDA) using a plane-wave pseudopotential implementation. Within the GW-approximation, we then calculate the quasi-particle energies (“true” single-particle excitation energies). In the third step, electron-hole attraction (excitonic effects) is included by solving the Bethe-Salpeter (BS) equation.

Calculation details: We use a trigonal array of tubes with minimum inter-wall distance of 20 a.u. in order to minimize inter-tube interaction and to simulate as closely as possible the properties of isolated tubes. The tubes are geometry-optimized (forces on the atoms less than 5 ×
the 3D bulk hBN compared to the binding energy of 0.7 eV that is found for increasing inter-sheet distance, approaching the limit of a quasi 2D isolated sheet, the excitonic binding energy increasing by a factor of four compared to the purely 2D limit, the binding energy for a hydrogenic electron-hole overlap in the reduced dimensionality (in 3D case). At the same time, the reduced dimensionality leads to an increased electron-electron correlation and thereby to an increase of the quasi-particle gap. Fig. 2 demonstrates that the increase of the quasi-particle gap almost exactly cancels the increase of the binding energy.

The position of the first absorption peak remains almost constant. What changes is the onset of the continuum. For the BN-sheet however, the absorption at the onset of the continuum is almost zero (also the higher excitonic peaks carry very low oscillator strength). The excitonic spectrum can therefore be calculated to a good approximation already with an inter-sheet distance of 20 a.u.

We made a similar series of calculations for the hypothetical BN(2,2) tube which has a diameter of 2.8 Å and is close to being a 1D system. Again, as we increase the inter-tube distance, the increase of the quasi-particle gap almost cancels the increase of the excitonic binding energy. While the latter converges towards a value higher than 3 eV, the absolute position of the first absorption peak remains constant to within 0.2 eV. In the following, we present therefore calculations for different tubes in a supercell geometry with 20 Å inter-wall distance. We remark that dimensionality effects would be more visible in other spectroscopic measurements such as photoemission spectroscopy, where we mainly map the quasiparticle spectra, and this (as the exciton binding itself) is sensitive to the change in screening going from the tube to the sheet to bulk hBN. In particular the quasi-particle band-gap will vary strongly with dimensionality (opening as dimensionality reduces).

In Fig. 2 we present the spectra of bulk hBN, of the single-sheet of hBN and of different BN nanotubes with diameters ranging from 2.8 Å (for the purely hypothetical BN(2,2) tube) to 9.7 Å (for the BN(7,7) tube) which is at the lower border of the range of experimentally produced tubes. The light polarization is set parallel to the planes or tube-axis, respectively. On the left hand side, we show the RPA spectra which are almost indistinguishable for the bulk and for the single-sheet. The selection rules only allow transitions between the π and π* bands (band 4 and 5 in the sheet). The band-structure of the tubes can be constructed via the zone-folding procedure, i.e., by cutting the 2D bandstructure of the sheet along certain discrete lines that correspond to quantized wave-vector along the circumferential direction. The RPA spectra of the tubes display therefore transitions at the same energies as in the sheet. (For a comparison of tube and sheet band-structures, see Refs. 1, 3, 14.) With increasing diameter, the shape of the tube spectra converges rapidly towards the sheet spectrum, in particular if plotted with a Lorentzian broadening of 0.1 eV (corresponding roughly to usual experimental values). A calculation with a fine broadening of 0.025 eV (and a correspondingly fine sampling with 200 k-points in the first Brillouin zone), reveals additional fine-structure below 5.5 eV. This structure is due to the van-Hove singularities in the one-dimensional density of states. For tubes with larger radii, the density of the fine-structure peaks increases and the RPA spectrum approaches that of the 2D sheet. The onset of absorption is constant at 4.7±0.1 eV for all tubes except for the (2,2) and the (6,0) tube (and other small diameter zigzag tubes) where the gap is lowered due to curvature effects.

While the RPA spectra are due to a continuum of inter-band transitions, the BS+GW optical spectra on the right-hand side of Fig. 2 are dominated by discrete excitonic peaks where the first peak comprises most of the oscillator strength. For bulk hBN, we have shown that the broadened excitonic spectrum properly reproduces the experimental spectral shape. The sheet spectrum...
FIG. 2: Optical absorption of (a) hBN, (b) BN-sheet, and (c) six different BN tubes with increasing diameter $d$. We compare the results of the GW + Bethe-Salpeter approach (right hand side) with the random phase approximation (left hand side). Solid lines are calculated with a Lorentzian broadening of 0.025 eV, dashed lines with a broadening of 0.1 eV (for comparison with experimental data). The light polarization is parallel to the plane/tube axis, respectively (except for the dotted line in the (6,6) case where the light polarization is perpendicular to the tube axis, see main text for discussion).

contains three bound excitonic peaks of rapidly decreasing intensity and absorption at the onset of the continuum is reduced to almost zero. As explained above, the stronger binding energy of the first bound exciton is almost compensated by an increase of the quasi-particle gap due to the reduced dimensionality. The same holds for the tube spectra: Except for the three smallest tubes, the position of the first and dominant excitonic peak remains constant. With increasing tube diameter, the spectrum rapidly converges towards the three-peak spectrum of the flat sheet. Also the onset of the continuum converges towards the value in the sheet (note that we compare here the values for a super-cell geometry with inter-sheet/inter-tube distance of 20 a.u.). The rapid convergence of the excitonic peaks is an indication for a strong confinement of the exciton wavefunction. Plotting the wavefunction, we have verified that this Frenkel type exciton is confined to within a few inter-atomic distances for either tubes, sheet or bulk hBN (see also the plot for an exciton in bulk hBN in Ref. [11]). With increasing tube diameter, the excitons only “see” a locally flat environment which explains the rapid convergence towards the sheet spectrum. The strongly localized nature of the exciton in BN structures makes the appearance of one-dimensional confinement effects very restricted to small diameter tubes, i.e, tubes for which the extension of the excitonic wavefunction is comparable to the nanotube circumference. This is usually the case for carbon nanotubes but not for the BN tubes as the excitonic wavefunctions only spans a few lattice constants. As the experimental tubes have diameters around 1.4 nm, the 1D-nature of the tubes cannot be observed and only the 2D nature of the local exciton environment (tube surface) controls the optical activity.

For the (6,6) tube, we display in Fig. 2 C) also the spectrum for light polarization perpendicular to the tube axis. The spectrum exhibits a major excitonic peak that lies slightly below the second excitonic peak obtained for light polarized along the tube axis. Note that the sheet is completely transparent up to 9 eV for light polarized
perpendicular to the plane.

We compare our results now to two recent contradictory measurements of the optical properties of BN nanotubes. In the EELS experiment of Arenal et al., the electron-beam passes the tube in the tangential direction. A detailed explanation of the spectral shape would require the calculation of the imaginary part of the polarizability $\alpha_{m,k}$, where $m$ is the index for the multipole expansion in circumferential direction and $k$ is the Fourier expansion along the tube axis. This is beyond the scope of this paper, where we only calculate the dipolar contribution ($m=0$) in the limit $k \to 0$. This is, however, the dominant part in the expansion of $\alpha$. The constancy of the first excitonic peak explains why the “optical gap” observed in Ref. 10 is always 5.8 eV, whether they measure bulk hBN, multi-wall tubes, or single-wall tubes. We note that there is a chirality dependence of the optical spectra but it is only visible for the smallest diameter tubes. The spectra of the armchair tubes converge much faster to the 2D case than the ones of the zig-zag tubes. However, as experimental tube diameters are much larger than the 5.1 Å of the (6,6) zigzag tube that is presented in this paper, we expect the chiral dependence to be marginal. Our calculations show that the explanation of Ref. 3 for the two peaks at 4.45 and 5.5 eV in their absorption spectra of a sample containing BN tubes does not hold: the peaks are neither due to additional Van-Hove singularities (since the spectra are entirely dominated by discrete excitonic peaks) nor can they be explained by an increased excitonic binding-energy (which is canceled by an increased quasi-particle gap).

So far, we have concentrated on singlet active excitons. For bulk hBN, we have shown previously that there is a dark singlet exciton and two triplet excitons below the first optically active exciton. For the single sheet (and light polarization parallel to the plane), we find that the lowest optically active exciton is doubly degenerate. There is no dark singlet exciton below, but a doubly degenerate triplet exciton at 0.1 eV lower energy. For the (6,6) tube (and light polarization parallel to the tube axis), we find that the degeneracy of the singlet exciton is lifted, leading to a dark singlet exciton slightly (0.01 eV) below the optically active singlet exciton. The degeneracy of the triplet exciton is lifted as well: the two triplet excitons are 0.1 eV and 0.08 eV lower in energy than the optically active singlet exciton. Similar results hold for the (5,5) and the (7,7) tubes. A recent study for C-tubes has shown that the room temperature luminescence is enhanced once the complete series of active and dark excitons is taken into account. This would hold also in the present case. Furthermore, due to the minor differences in the optical spectra of tubes and bulk BN we expect the BN-tubes to exhibit a strong ultraviolet lasing behavior as already observed for bulk BN. The fact that this luminescence response would be rather insensitive to tube diameter and chirality makes the BN tubes ideal candidates for optical devices in the UV regime as the carbon nanotubes are in the infrared regime. The photoluminescence quantum yield of BN tubes should surpass the efficiency of carbon.

In conclusion, the optical absorption spectra of hBN and BN nanotubes are dominated by excitonic effects. Most oscillator strength is collected by the first bound exciton. Its binding energy increases strongly as the dimensionality is reduced from the 3-D bulk over the 2-D sheet to the 1-D tubes. At the same time the quasiparticle band gap increases with reduced dimensionality. This cancellation leaves the absolute position of the dominant absorption peak almost constant.

We acknowledge helpful discussions with D. Varsano, V. Olevano, and L. Reining. The work was supported by the EU network of excellence NANOQUANTA (NMP4-CT-2004-500198) and the French GDR "nanotubes". Calculations were performed at IDRIS (Project No. 51827) and CEPBA. A.R. acknowledges the Humboldt Foundation under the Bessel research award (2005)

20 This procedure yields a quasi-particle bandgap for the single sheet and for the tubes that is about 0.25 eV higher than the one obtained on the non-self consistent ($G_0W_0$) level. Still, for bulk hBN we have shown that this $G_0W_0$ calculation starting from LDA wave-functions yields a quasi-particle band-gap that is too low by 0.65 eV. In the present work, we assume that the same underestimation of the LDA $G_0W_0$ band-gap holds also for the single sheet and for the tubes. Consequently, we add a 0.65 eV “scissor” shift to the calculated $G_0W_0$ band-structure.
