We consider exact time-dependent analytic solutions to the Schrödinger equation for tunneling in one dimension with cut off wave initial conditions at $t = 0$. We obtain that as soon as $t \neq 0$ the transmitted probability density at any arbitrary distance rises instantaneously with time in a linear manner. Using a simple model we find that the above nonlocal effect of the time-dependent solution is suppressed by consideration of low-energy relativistic effects. Hence at a distance $x_0$ from the potential the probability density rises after a time $t_0 = x_0/c$ restoring Einstein causality. This implies that the tunneling time of a particle can never be zero.

Recent technological achievements as the possibility of constructing artificial quantum structures at nanometric scales [1] or manipulating individual atoms [2] have stimulated a great deal of work at both an applied and fundamental level. In particular, studies on tunneling have addressed, among others, the controversial question of the traversal time of a particle through a classically forbidden region [3]. The above considerations have motivated a renewed attention to the time-dependent treatments of quantum tunneling. From the theoretical side, most of these works are based on the numerical analysis of the time-dependent Schrödinger equation with the initial condition of a Gaussian wave packet [4]. A common feature in most of these approaches is that the initial wave packet extends through all space. As a consequence the initial state, although it is manipulated to reduce as much as possible its value along the tunneling and transmitted regions, contaminates from the beginning the tunneling process. In the literature, however, one also finds a number of approaches to time-dependent tunneling, pioneered by Stevens [5], that in fact circumvent the above situation using a cut off wave as initial state [6].

Our approach is a generalization to an arbitrary potential [7] of the Moshinsky shutter [9]. Moshinsky considered the solution of the time-dependent free Schrödinger equation with the initial condition, at $t = 0$, of a plane wave of momentum $k$ confined in the half-space region $x < 0$ to the left of a perfectly absorbing shutter located at $x = 0$. The sudden opening of the shutter at time $t = 0$, allows the plane wave solution to propagate freely along the region $x > 0$ [10]. Moshinsky showed that as the time $t$ goes to infinity, the solution to the problem tends to the stationary solution. He also found that both the current and the probability density for a fixed value of the distance $x_0$ as a function of $t$, present oscillations near the wavefront, situated at $t_0 = x_0/v$. He named this phenomenon diffraction in time, in analogy to the well known phenomenon of optical diffraction. Recently an observation of diffraction in time has been reported [11]. If we put a potential barrier in the region $0 \leq x \leq L$ with the same initial condition as above, then we may have a convenient model to analyze tunneling times by measuring at what time the probability density rises from zero. However, as pointed out by Holland [12] for the free case, and by García-Calderón and Rubio [8], for the case of a potential, the solution of the time-dependent Schrödinger equation for a cut off initial plane wave has a nonlocal character. This means that if initially there is a zero probability for the particle to be at $x > 0$, as soon as $t \neq 0$, there is instantaneously a finite, though very small, probability to find it at any point $x > 0$. This implies a zero tunneling time for some particles.

In this work we address the issue of the behaviour of the time-dependent solution to the Schrödinger equation for tunneling through a potential barrier using a cut off wave as initial condition. Our aim is to analyze the nonlocal behaviour of the time-dependent transmitted solu-
In terms of the resonant eigenfunctions \( T \), the transmitted solution for the region \( x \geq L \) vanishes outside the region \( 0 \leq x \leq L \), with the initial condition,

\[
\psi_s(x, k, t = 0) = \begin{cases} 
  e^{ikx}, & x < 0 \\
  0, & x > 0.
\end{cases}
\]  

(1)

The transmitted solution for the region \( x \geq L \) reads [3],

\[
\psi_s(x, k, t) = T(k)M(x, k, t) - i\sum_n T_n M(x, k_n, t),
\]  

(2)

where \( T(k) \) stands for the transmission amplitude of the problem, \( T_n = u_n(0)u_n(L)\exp(-ik_nL)/(k - k_n) \), is given in terms of the resonant eigenfunctions \( u_n(x) \) and complex S-matrix poles \( k_n \); and the Moshinsky functions \( M(x, k, t) \) and \( M(x, k_n, t) \) are defined as,

\[
M(x, q, t) = \frac{1}{2} e^{ikx/2ht} e^{\frac{1}{2}h} \text{erfc}(y),
\]  

(3)

where the argument \( y \) is given by

\[
y = e^{-\frac{im}{4}} \left( \frac{m}{2ht} \right)^{1/2} \left[ x - \frac{h}{m} \right].
\]  

(4)

In the above two equations \( q \) stands either for \( k \) or \( k_n \).

In the absence of a potential the solution given by Eq. (2) becomes the solution for the free case obtained by Moshinsky [3],

\[
\psi_s^0(x, k, t) = M(x, k, t).
\]  

(5)

As discussed by Moshinsky, the initial condition given by Eq. (5) refers to a shutter that acts as a perfect absorber (no reflected wave). One can also envisage a shutter that acts as a perfect reflector. In such a case the initial wave may be written as,

\[
\psi_s(x, k, t = 0) = \begin{cases} 
  e^{ikx} - e^{-ikx}, & x < 0 \\
  0, & x > 0.
\end{cases}
\]  

(6)

The transmitted solution for the region \( x \geq L \) now reads,

\[
\psi_s(x, k, t) = T(k)M(x, k, t) - T(-k)M(x, -k, t)
\]

\[-2ik\sum_n T_n M(x, k_n, t),
\]

(7)

where \( T_n = u_n(0)u_n(L)\exp(-ik_nL)/(k^2 - k_n^2) \). The solution for the free case with the reflecting initial condition is

\[
\psi_s^0(x, k, t) = M(x, k, t) - M(x, -k, t).
\]  

(8)

The exact solutions given by Eqs. (2) and (5), corresponding, respectively, to absorbing and reflecting initial cut off waves, involve each a contribution proportional to the free case solution and then an infinite sum involving the S-matrix poles, \( \{k_n\} \), and resonant states, \( \{u_n(x)\} \), of the system. As shown in ref. [3], at very long times, the terms \( M(x, k_n, t) \) that appear in the above equations vanish. The same occurs for \( M(x, -k, t) \) while, as shown firstly in ref. [9], \( M(x, k, t) \) tends to the stationary solution. Hence, at long times, each of the above exact solutions go into the stationary solution \( T(k)\exp[i(kx - Et/\hbar)] \).

At very short times, for a given \( x \geq L \), the argument of \( M(x, k, t) \), given by Eq. (4) with \( q = k \), becomes very large and in fact becomes independent of the value of \( k \), 

\[
y \approx \exp(-i\pi/4)[m/(2ht)]^{1/2}/x.
\]

Since for very large \( y \), \( M(y) \sim 1/y \), it follows that \( M(x, k, t) \) goes like \( t^{1/2} \).

As discussed also in ref. [3], the functions dependent on the poles, \( M(x, k_n, t) \), behave in a similar fashion provided the value of \( t = t_0 \) is sufficiently small to guarantee, for a fixed \( x = L \), that \( L \gg h/k_n|m| \). Since the distribution of the complex S-matrix poles on the \( k \)-plane fulfills \([|k_1| < |k_2| \ldots < |k_n| \ldots, one sees that as \( t \) becomes smaller and smaller there will be more and more values of \( n \) for which the corresponding \( M \) functions go like \( t^{1/2} \) as do all the rest of \( M \) functions associated with smaller values of \( n \). In the appropriate limit as \( t \to 0 \) and \( n \to \infty \), the corresponding \( M \) function then vanishes as \( t^{1/2} \). Consequently for \( x \geq L \), the solutions given by Eqs. (2) and (5) are proportional to \( t^{1/2} \), namely,

\[
\psi_s(x, k, t) \sim \frac{A}{x} t^{1/2}, \quad (x \geq L)
\]  

(9)

where \( A \) a constant. Note that at \( t = 0 \) the solution vanishes in accordance with the initial condition. It is not difficult to see that Eq. (9) will hold also for a cut off initial condition that is something between the initial conditions considered above, and more generally, for a wave packet formed by a linear combination of cut off waves. Eq. (9) tell us that the probability density at any distance \( x \) from the potential will rise instantaneously with time. This intriguing nonlocal behaviour implies that an ideal detector will measure a zero tunneling time. The existence of action-at-a-distance effects in the time-dependent Schrödinger equation should not in
principle pose any conceptual difficulties since the treatment is non-relativistic. However one could ask whether the above nonlocal behaviour arises because the initial condition is a cut off wave. In order to answer the above question we consider low-energy relativistic effects by solving the Klein-Gordon equation with a cut off wave as initial condition for a simple potential model. Moshinsky solved the Klein-Gordon equation for the free shutter problem with the initial condition of a cut off plane wave in the region \( x < 0 \) and that the probability density at a point \( x > 0 \) is nonzero only after a time \( t_0 > x_0/c \), with \( c \) the velocity of light. To our knowledge a numerical analysis of this solution has not yet been performed. We would like to learn also how the relativistic solution is affected at early times by tunneling through a potential.

A potential that has been widely used in studies on time-dependent tunneling is the square barrier, characterized by a height \( V_0 \) and a width \( L \). This potential has an infinite set of \( S \)-matrix poles situated at increasing energies on top of the barrier. There is, however, a simpler potential model that is more amenable for a relativistic treatment. This is the delta potential \( \delta \). The solution corresponding to the time-dependent Schrödinger equation has been obtained by Elberfeld and Kleber using a delta-function propagator. One can also follow a derivation by Laplace transforming the solution of the free Klein-Gordon case, namely, the transmission amplitudes for the stationary situation, 

\[
\psi^T(x, k_r, t) = \int_{-\infty}^{\infty} \frac{\partial}{\partial x} \frac{\psi^\delta(x, k_r, t)}{\sqrt{2c}} e^{ik_xt} \frac{\eta}{\sqrt{2\pi}} J_0(\eta) \eta^{-\frac{1}{2}}.
\]

where \( \eta = k_r + Ev_0 \). With \( \eta \), the function \( \psi^\delta(x, k_r, t) \) is the solution of the free Klein-Gordon equation with the delta potential \( \delta \).

The delta potential \( \delta \) is non-relativistic. However one could ask whether the above nonlocal behaviour arises because the initial condition is a cut off wave.

In order to answer the above question we consider low-energy relativistic effects by solving the Klein-Gordon equation with a cut off wave as initial condition for a simple potential model. Moshinsky solved the Klein-Gordon equation for the free shutter problem with the initial condition of a cut off plane wave in the region \( x < 0 \) and that the probability density at a point \( x > 0 \) is nonzero only after a time \( t_0 > x_0/c \), with \( c \) the velocity of light. To our knowledge a numerical analysis of this solution has not yet been performed. We would like to learn also how the relativistic solution is affected at early times by tunneling through a potential.

A potential that has been widely used in studies on time-dependent tunneling is the square barrier, characterized by a height \( V_0 \) and a width \( L \). This potential has an infinite set of \( S \)-matrix poles situated at increasing energies on top of the barrier. There is, however, a simpler potential model that is more amenable for a relativistic treatment. This is the delta potential \( \delta \). The solution corresponding to the time-dependent Schrödinger equation has been obtained by Elberfeld and Kleber using a delta-function propagator. One can also follow a derivation by Laplace transforming the solution of the free Klein-Gordon case, namely, the transmission amplitudes for the stationary situation, 

\[
\psi^T(x, k_r, t) = \int_{-\infty}^{\infty} \frac{\partial}{\partial x} \frac{\psi^\delta(x, k_r, t)}{\sqrt{2c}} e^{ik_xt} \frac{\eta}{\sqrt{2\pi}} J_0(\eta) \eta^{-\frac{1}{2}}.
\]

where \( \eta = k_r + Ev_0 \). With \( \eta \), the function \( \psi^\delta(x, k_r, t) \) is the solution of the free Klein-Gordon equation with the delta potential \( \delta \).
the terms \( \psi_0^0(x, -ib_0, t) \) and \( (\psi_0^0(x, -ib_0, t))^* \) vanish, while the term \( \psi_0^0(x, k_v, t) \) goes into the stationary solution \( \exp[i(k_v x - E_v t)] \).

To exemplify the above results Fig. 1 exhibits the very short time behaviour of the probability density for the delta potential at a fixed distance \( x = L = 0.3 \AA \). One sees that the Schrödinger description (broken line), obtained from Eq. (11) with parameters \( b_s = 2.0 \text{ eV} - A \) and \( E = 0.01 \text{ eV} \), yields an instantaneous response with time while the relativistic solution, calculated using Eq. (13), starts after \( t_0 = L/c \). This tells us something relevant: The nonlocal behaviour of the Schrödinger description is due to its non-relativistic nature. The non-local behavior of the Schrödinger solution would result from the fact that in a non-relativistic description there is no restriction on the velocity of some components of the initially confined wave function. The sharp relativistic wavefront of height 0.25 in Fig. 1 follows as a consequence of the initial condition given by Eq. (13). This jump occurs also in the free case and may be obtained analytically. For an initial function of the type \( \exp(ik_v x) + \exp(i\alpha)\exp(-ik_v x) \), \( x < 0 \), with \( \alpha \) an arbitrary phase, the peak height will be a function of \( \alpha \). In particular, for a reflecting initial condition, \((\alpha = \pi)\), the solution starts smoothly from zero at \( t_0 = L/c \). It might be of interest to mention that in fully relativistic quantum field theories Hegerfeldt \( ^{[17]} \) has pointed out that the sudden opening of a shutter may lead to violation of Einstein causality, i.e., no propagation faster than light. This author has argued that the difficulty is of a theoretical nature and has discussed some ways to solve it. Our relativistic model satisfies Einstein causality. The inset to Fig. 1 shows that at longer times the above two solutions approach each other, both presenting the characteristic transient behaviour near the ‘classical’ wavefront at \( x = vt \), which in our example occurs at a very short time. Our analysis has a consequence of interest for the tunneling time problem. Since the probability density rises with time after a time \( t_0 = x_0/c \), it implies that the tunneling time of a particle can never be zero, contrary to some claims in the literature.\( ^{[3]} \)

Thus we can see that a proper description of the quantum mechanical propagation for the transmitted solution, even at low energies, strictly requires a relativistic treatment. However, since the corresponding solutions are practically identical up to the relativistic cut off, at \( t = L/c \), suggests that the Schrödinger description is quite accurate provided the velocity components larger than \( c \) are omitted.
