Abstract
We examined depression and anxiety prior to and during COVID-19 restrictions in Australian gay and bisexual men (GBM). In an online cohort, a COVID-19-focused survey was conducted in April 2020. During 2019 and in April 2020, 664 GBM completed the Patient Health Questionnaire (PHQ-9, measuring depression) and Generalized Anxiety Disorder Assessment (GAD-7, measuring anxiety). Increased depression and anxiety were defined as a ≥ 5 point increase on the respective scales. Mean PHQ-9 and GAD-7 scores increased between 2019 and 2020 (PHQ-9: from 5.11 in 2019 to 6.55 in 2020; GAD-7: from 3.80 in 2019 to 4.95 in 2020). The proportion of participants with moderate-severe depression (PHQ-9 ≥ 10) increased from 18.8% (n = 125) to 25.5% (n = 169), while the proportion of participants with moderate-severe anxiety (GAD-7 ≥ 10) increased from 12.7% (n = 84) to 17.3% (n = 115). Almost one-quarter of participants (n = 158, 23.8%) had increased depression; in these men, mean PHQ-9 increased from 2.49 in 2019 to 11.65 in 2020 (p < 0.001). One-in-five (20.6%) participants (n = 137) had increased anxiety; among these men, mean GAD-7 increased from 2.05 in 2019 to 10.22 in 2020 (p < 0.001). Increases were associated with concerns about job security, reduction in social and sexual connections and opportunities, and being personally concerned about COVID-19 itself. COVID-19 appeared to have a sudden and pronounced impact on depression and anxiety in Australian GBM, with a significant minority showing sharp increases. Ongoing monitoring is required to determine longer-term impacts and GBM need access to appropriate and sensitive supports both during and after the COVID-19 pandemic.

Keywords Gay and bisexual men · Mental health · COVID-19 · Depression · Anxiety · Sexual orientation

Introduction
Severe Acute Respiratory Syndrome coronavirus-2 (SARS-CoV-2), the cause of COVID-19, is highly transmissible through close proximity with an infected person (Guan et al., 2020; Guo et al., 2020). From early March through late April 2020, Australian jurisdictions implemented restrictions in response to COVID-19. During initial “shutdown” periods, people could leave their homes for essential shopping, to provide care or seek medical treatment, to exercise, or to commute to work/study if not possible from home, and were advised to restrict sexual encounters to established intimate partners (COVID-19 National Incident Room Surveillance Team, 2020).

Research in Australia and elsewhere has documented impacts of COVID-19 restrictions on mental health in the general population, including increased feelings of stress and isolation, and producing or exacerbating mental health problems (Fisher et al.,
Social connection and support are protective against declines in mental health during the pandemic (Cao et al., 2020). While the COVID-19 pandemic presents mental health challenges for the general population, physical distancing restrictions may have specific impacts on gay and bisexual men (GBM), who typically have higher prevalence of mental ill-health than the general population (King et al., 2008; Meyer, 2003; Prestage et al., 2018). Restrictions associated with COVID-19 may prevent GBM from accessing critical sexuality-affirming supports (Brennan et al., 2020; Santos et al., 2020; Suen et al., 2020). Peer support among GBM and engagement with gay community have been found to counter negative mental health effects, increase health-seeking behaviors, and assist men to find a sense of belonging (Anderson & Knee, 2021; Hammoud et al., 2017; Mao et al., 2009; Prestage et al., 2018). Cross-sectional research has documented emerging concerns about the mental health of GBM due to COVID-19, with studies during the COVID-19 period finding that just under one-third of GBM experienced depression or anxiety (Santos et al., 2020; Suen et al., 2020), that those who practiced physical distancing were more likely to feel anxious (Holloway et al., 2021), and another reporting that over half felt they needed help with a mental health problem (Brennan et al., 2020). A systematic review from the United Kingdom found that mental health and well-being outcomes were poorer among lesbian, gay, bisexual, and transgender (LGBT) people, but the low data quality was noted (McGowan et al., 2021). Researchers have called for specific monitoring of sexual minorities and mental health during the COVID-19 pandemic (Phillips et al., 2020). In the context of pre-existing, disproportionate burden of mental ill-health among GBM, coupled with a higher likelihood of experiencing co-occurring challenges such as stigma and discrimination (Victorian Agency for Health Information, 2020), mental health services (and funders) need to be cognizant of the unique needs of this population during the pandemic.

Our ongoing cohort of Australian GBM provided an opportunity to explore the impact of COVID-19 on depression and anxiety in this population. This analysis aimed to: (1) Determine changes in symptoms of depression and anxiety after the initial implementation of COVID-19 physical distancing restrictions, including trends between 2015 and 2020; and (2) Identify factors associated with increased symptoms of depression and anxiety after the initial implementation of COVID-19 physical distancing restrictions.

**Method**

**Participants and Procedure**

The *Following Lives Undergoing Change (Flux) Study* is a national, online, prospective observational study of GBM in Australia, launched in 2014. The study protocol has been published (Hammoud et al., 2017). Men were eligible to participate in the study if they were ≥16 years of age, identified as gay or bisexual or had sex with a man in the previous 12 months, and lived in Australia. Participants provided informed consent by selecting a checkbox on the online survey indicating they had read and understood the requirements of participating in the study. No compensation was offered for participation. Ethical approval was provided by UNSW Sydney.

The study was promoted by online advertising on social media and gay sexual networking sites/apps. Participants completed online surveys at six-monthly intervals. In early April 2020, participants were invited to complete a survey round with new questions assessing the impact of COVID-19. Men were included in this analysis if they: (1) had participated in a *Flux* survey during 2019 and completed the depression and anxiety measures at least once (for participants with two 2019 surveys, analysis was based on the more recent data); and (2) participated in the 2020 COVID-19 round and provided complete responses to the depression and anxiety measures.

**Measures**

Depression was measured using the Patient Health Questionnaire (PHQ-9; scale range = 0–27) (Kroenke et al., 2001) and anxiety was measured using the Generalized Anxiety Disorder Assessment (GAD-7; scale range = 0–21) (Spitzer et al., 2006). Both are well-established instruments and align closely with diagnostic criteria for major depressive disorder and generalized anxiety disorder, respectively (Kroenke et al., 2010). Patients rated each symptom from 0 (not experienced) to 3 (experienced every day). Scale scores were calculated for each participant. A score of 10 on each scale was considered the clinical cut-off for symptoms consistent with depression or anxiety, and were termed “moderate-severe” depression or anxiety, respectively (Kroenke et al., 2001). Following McMillan et al. (2010), a ≥ 5 point increase between 2019 and the 2020 COVID-19 round on the PHQ-9 or GAD-7 was taken as a clinically significant and meaningful increase in symptoms of depression or anxiety, respectively.

Questionnaires included demographic items such as age, country of birth, and sexual identity; self-reported HIV serostatus and testing histories; and sexual behaviors with male partners. A validated measure of sexual sensation-seeking was included to measure the propensity to seek out novel or risky sex (scale range = 11–44) (Kalichman & Rompa, 1995), as was a reliable two-item scale measuring “gay social engagement” (GSE; number of gay friends and amount of time spent with gay men; scale range = 0–7) (Zablotska et al., 2011). Participants reported their postcode of residence. Using a previously published method estimating the proportion of men identifying as gay in every Australian postcode (Callander et al., 2020), we classified a postcode as a “gay
suburb” if the proportion of gay-identified men was in the 95th percentile or greater (with an average of approximately 10% of resident men identifying as gay). COVID-19-related items were developed by the study team to measure changes in sexual behaviors, social behaviors, attitudes, employment, and experiences of COVID-19 since physical distancing measures were first implemented in Australia.

Statistical Analysis

Analysis was conducted using Stata version 14.2 (StataCorp, College Station, TX). Trends among the included men were examined from 2015 to 2020. Mean differences in scale scores were compared using paired-samples $t$-tests; these focused on means from 2019 and 2020, but for sensitivity, also between 2018 and 2020. Factors associated with increased depression and anxiety were identified in bivariate analysis with $t$-tests for continuous variables and chi-square tests for categorical variables. In multivariate analysis, factors independently associated with increased symptoms were identified using logistic regression; we present adjusted odds ratios (aOR), 95% confidence intervals (95% CI) and $p$-values.

Results

The PHQ-9 and GAD-7 were completed by 913 men in the 2020 COVID-19 survey, and of these, 664 also completed the measures in 2019. Compared to the 664 included men, the 249 men who did not complete them in 2019 were younger ($p = 0.003$); less likely to have a university qualification ($p = 0.039$); and had higher mean scores on the PHQ-9 ($p = 0.002$) and the GAD-7 ($p = 0.001$) in 2020. They were not different in terms of other demographic indicators, HIV status, or mean GSE scale scores. Included participants had a median age of 44 years (IQR = 34–56), and 72.4% ($n = 481$) were university educated. One-quarter ($n = 172, 25.9\%$) lived in a “gay postcode.” Most were born in Australia ($n = 532, 80.1\%$) and had an Anglo-Celtic ethnicity ($n = 525, 79.1\%$). Most were HIV-negative ($n = 591, 89.0\%$), while 7.7% ($n = 51$) were HIV-positive, and 3.3% ($n = 22$) were untested or had unknown HIV status. There was a statistically significant decrease in mean GSE scores between 2019 ($M = 3.95, SD = 1.54$) and 2020 ($M = 3.54, SD = 1.53, p < 0.001$).

Depression

Figure 1a shows mean PHQ-9 scores over time, from 2015 to 2020, among the 664 men included in the analysis. In the five years before 2020, the average mean PHQ-9 score was 5.61 (range = 5.11–5.90). The mean PHQ-9 score was 5.11 (SD = 5.99) in 2019 and 6.55 (SD = 6.00) in the 2020 COVID-19 survey ($t = –6.53, p < 0.001$). To account for the significant decrease between 2018 and 2019 ($t = 2.69, p < 0.001$), we also examined the increase between 2018 and 2020, which was also statistically significant ($t = –3.15, p = 0.002$). The proportion of participants with moderate-severe depression (i.e. PHQ-9 score of ≥ 10) increased from 18.8% ($n = 125$) to 25.5% ($n = 169$; Fig. 1b). Further details on the scale categories are presented in Supplementary Table S1.

Between 2019 and 2020, 158 participants (23.8\%) increased ≥ 5 points on the PHQ-9, indicating reliably increased symptoms of depression (hereafter referred to “increased depression”). Within these 158 men, mean PHQ-9 increased from 2.49 (SD = 4.03) in 2019 to 11.65 (SD = 5.51) in 2020 ($t = –27.05, p < 0.001$). While 7.6\% ($n = 12$) of these 158 participants had a PHQ-9 of ≥ 10 in 2019, this increased to 55.7\% ($n = 88$) in 2020.

In bivariate analyses, compared to the 506 men without increased depression, those with increased depression ($n = 158$) were more likely to: be living with housemates ($p = 0.028$); have been laid off temporarily or permanently from work ($p = 0.002$); be concerned about losing their job

![Fig. 1 Trends in depression and anxiety, 2015 to 2020: a Mean scale score; b Proportion of sample with scale score > 10, PHQ-9, Patient Health Questionnaire; GAD-7, Generalized Anxiety Disorder Assessment. The grey line on the figures refers to the final pre-COVID-19 survey round](image-url)
due to COVID-19 \( (p < 0.001) \); have found it very difficult to stop going out for entertainment \( (p = 0.004) \); have found it very difficult to stop kissing/hugging friends and family \( (p < 0.001) \); have found it very difficult to not have sex with new partners \( (p = 0.006) \); have lost contact with people they cared about \( (p < 0.001) \); be younger \( (p = 0.001) \); and have had higher mean GSE score in 2019 \( (p = 0.040) \) (Table 1). They were less likely to have received support from work colleagues \( (p = 0.032) \) (Table 1). Among the 51 HIV-positive men, very few \( (n = 6) \) reported difficulties accessing their HIV medications, and this was not associated with increased depression \( (p = 0.502) \). Similarly, in total only two HIV-positive participants experienced changes in their viral load, and this was also not associated with increased depression \( (p = 0.781) \). In multivariate logistic regression, factors independently associated with increased depression were: concern about losing their job \( (\text{aOR} = 2.03, 95\% \text{ CI} = 1.19–3.48, p = 0.009) \); having lost contact with people they cared about \( (\text{aOR} = 2.28, 95\% \text{ CI} = 1.32–3.92, p = 0.003) \); and a higher GSE in 2019 \( (\text{aOR} = 1.30, 95\% \text{ CI} = 1.10–1.54, p = 0.003) \) (Table 2).

### Anxiety

Between 2015 and 2019, mean GAD-7 scores averaged at 4.10 \( \text{(range} = 3.80–4.60; \text{Fig. 1a}) \). Mean GAD-7 was 3.80 \( \text{(SD} = 4.78) \) in 2019 and increased to 4.95 \( \text{(SD} = 5.05) \) in 2020 \( (t = –6.05, p < 0.001) \). Again, to account for the drop between 2018 and 2019 \( (t = 1.12, p < 0.001) \), the increase between 2018 and 2020 was also statistically significant \( (t = –3.81, p < 0.001) \). The proportion of participants with moderate-severe anxiety \( (\text{i.e. GAD-7 score of} \geq 10) \) increased from 12.7\% \( (n = 84) \) to 17.3\% \( (n = 115; \text{Fig. 1b}) \). Further details on the scale categories are presented in Supplementary Table S1.

One-in-five \( (n = 137) \) participants increased \( \geq 5 \) points on the GAD-7, indicating reliably increased symptoms of anxiety \( (\text{hereafter referred to as ‘increased anxiety’}) \). Within these 137 men, mean GAD-7 increased from 2.05 \( \text{(SD} = 3.48) \) in 2019 to 10.22 \( \text{(SD} = 4.69) \) in 2020 \( (t = –27.27, p < 0.001) \). While only 5.8\% \( (n = 8) \) of these 137 participants had a GAD-7 of \( \geq 10 \) in 2019, this increased to 41.6\% \( (n = 58) \) in 2020.

In bivariate analyses, compared to those without increased anxiety \( (n = 527) \), those with increased anxiety \( (n = 137) \): were concerned about losing their job due to COVID-19 \( (p = 0.004) \); found it very difficult to stop kissing/hugging friends and family \( (p < 0.001) \); found it very difficult to not have sex with new partners \( (p = 0.025) \); were concerned about contracting COVID-19 \( (p = 0.003) \); were concerned about transmitting COVID-19 to others \( (p = 0.010) \); were concerned about getting sick with COVID-19 \( (p = 0.015) \); were concerned about overwhelming the health system \( (p = 0.042) \); had lost contact with people they cared about \( (p < 0.001) \); and scored higher on sexual sensation-seeking in 2019 \( (p = 0.030) \) (Table 1). Among the 51 HIV-positive men, difficulty accessing HIV medication \( (p = 0.273) \) and change in viral load \( (p = 0.496) \) were not associated with increased anxiety. In multivariate logistic regression, factors independently associated with increased symptoms of anxiety were: finding it very difficult to stop hugging/kissing friends and family \( (\text{aOR} = 1.83, 95\% \text{ CI} = 1.09–3.09, p = 0.022) \); and concern about overwhelming the health system \( (\text{aOR} = 2.98, 95\% \text{ CI} = 1.02–8.76, p = 0.047) \) (Table 2).

### Discussion

Our results showed an increase in both depression and anxiety among GBM, coinciding with the COVID-19 pandemic and introduction of physical distancing restrictions in Australia. To our knowledge, these are the first such longitudinal data among GBM internationally. We found pre-COVID-19 levels of depression and anxiety were higher in our sample of GBM than in general population studies using the same measures \( \text{(Stocker et al., 2021)} \). General population studies in high-income countries have reported the prevalence of moderate-to-severe depression at 3.0\%–10.8\% and moderate-to-severe anxiety at 6.9\%–10.6\% \( \text{(Stocker et al., 2021)} \). By contrast, studies using the same measures in GBM have reported prevalence of depression at 12.5\%–28.3\% \( \text{(Ferlatte et al., 2019; Prestage et al., 2018; Sewell et al., 2017)} \) and of anxiety at 10.6\%–18.0\% \( \text{(Prestage et al., 2018; Sewell et al., 2017)} \). In Australia, a 2007 national survey found that homosexual/bisexual participants had 3.2 times the prevalence of affective disorders \( \text{(including depression)} \) and 2.2 times the prevalence of anxiety disorders compared to heterosexual participants \( \text{(Australian Bureau of Statistics, 2008)} \).

From these already high baseline levels, we observed a 28\% relative increase in PHQ-9 mean scores and a 30\% relative increase in GAD-7 mean scores between 2019 and the 2020 COVID-19 survey. In 2020, one-quarter of participants screened positively for moderate-severe depression and 17\% moderate-severe anxiety, similar to levels found in cross-sectional studies of the general Australian population during COVID-19 \( \text{(Dawel et al., 2020; Fisher et al., 2020)} \). Nearly one-quarter of participants had increased depression, while one-fifth had increased anxiety. These changes were associated with a range of factors including concerns about job security and work, reduction in social and sexual connection or opportunities, and concerns related to acquiring or transmitting COVID-19 or impacts on the health system.

Some studies examined mental health among GBM in the early COVID-19 pandemic. In an online survey of lesbian, gay, and bisexual people in Hong Kong, 31.5\% of participants met the condition for clinical depression and 27.9\% for anxiety, while 34.7\% reported reduced contact and connection with other GBM due to COVID-19 restrictions \( \text{(Suen et al., 2020)} \).
Table 1: Bivariate associations with increased symptoms consistent with depression (≥ 5-point increase in PHQ-9 score) and increased symptoms consistent with anxiety (≥ 5-point increase in GAD-7 score)

| Symptoms of depression | | Symptoms of anxiety | |
|------------------------|------------------------|------------------------|------------------------|
| Did not increase (n = 506) | Increased (n = 158) | p-value | Did not increase (n = 527) | Increased (n = 137) | p-value |
| N (%) | | | | | |
| Employment prior to COVID-19 | | | | | |
| Full-time | 331 (65.4) | 99 (62.7) | 0.200 | 345 (65.5) | 85 (62.0) | 0.139 |

et al., 2020). A global online survey of 2732 GBM across 103 countries conducted in April–May 2020 found that 35% screened positive for depression and 34% for anxiety (Santos et al., 2020). These studies reported higher prevalence than found in our data, but the participants were sampled from different countries with varying COVID-19 epidemics and human rights frameworks. As cross-sectional studies like these could not measure depression and anxiety pre- and post-COVID-19 restrictions, it limits their ability to attribute mental health problems to COVID-19 or other factors (Suen et al., 2020). In a large population-based longitudinal study of the general population in the United Kingdom (UK), clinically significant levels of mental distress rose from 18.9% in 2018–19 to 27.3% one month into the COVID-19 restrictions in the UK; it was reported that the increase in mean scores on the General Health Questionnaire (GHQ-12) was greater than expected by the pre-existing trend (Pierce et al., 2020). Outside of our study, similar longitudinal data do not appear to be available for GBM.

Several factors relating to employment were associated with increased depression/anxiety. Losing employment due to COVID-19 was associated with depression, while concern about losing employment was associated with both depression and anxiety (including at the multivariate level for depression). This supports other research in the general population (Fisher et al., 2020; Pierce et al., 2020) and with sexual minorities (Suen et al., 2020), showing that employment-related impacts are an important mental health stressor during the pandemic.

Concerns about COVID-19 itself, such as being worried about contracting it, transmitting it to others, getting sick, or overwhelming the health system, were associated with increased anxiety but not depression. In multivariate analysis, concern about overwhelming the health system was one of only two factors independently associated with increased anxiety. In both those with increased symptoms of anxiety and those without, the factors relating to concern for others (i.e. transmitting to others and overwhelming the health system) were of greater concern to participants than factors relating to concern for the self (i.e. contracting and getting sick with COVID-19).

Interestingly, while some factors related to sexual practice were associated with increased depression/anxiety, such as finding it very difficult to forego sex with new partners (associated with both depression and anxiety) or sexual sensation-seeking (associated with anxiety), actual reductions in sex with casual partners or “fuckbuddies” during COVID-19 restrictions were not. The mental health effects of COVID-19 restrictions thus appeared to be more related to desire and expectations about sex rather than actual changes in behavior. Relationship status was also not associated with increased depression or anxiety, counter to some international research showing that being in a relationship is protective against depression (Suen et al., 2020). On the other hand, greater social engagement with other gay men prior to (but not during) COVID-19 was strongly associated with increased depressive symptoms, suggesting that men who socialized more with gay friends before COVID-19 struggled more with the restrictions than men who were less socially engaged. Alternatively, it could be that protective aspects of spending time with other gay men (such as camaraderie, enjoyment, and support) were disrupted. Items relating to loneliness more generally were associated with increased symptoms of both depression and anxiety (Dawel et al., 2020), as was experiencing difficulties due to reducing physical contact (hugging/kissing) with friends and family.

Initial increases in depression and anxiety among GBM after physical distancing restrictions were introduced may represent a short-term “spike,” which may fall as people adjust or restrictions ease (Pierce et al., 2020). However, other trends may also occur, such as stabilization at a higher level, or even further increases (e.g. if restrictions are reimposed, if restrictions continue for extended periods, or if there are delays in vaccine distribution). Differential geographic impacts of COVID-19 are highly likely to be relevant. In Australia, physical distancing restrictions are largely implemented at the state level. While all jurisdictions had initial success in containing COVID-19, they had varying levels of success thereafter. More populous states such as New South Wales and Victoria experienced stricter restrictions. In particular, residents of Melbourne, Victoria, were placed under one of the strictest lockdowns globally from July to October 2020 (Victoria State Government, 2020), impacting the ability to make and maintain social and sexual connections and placing limitations on employment for many people. We will examine these issues in a future analysis of an ongoing COVID-19-related extension to the Flux Study whereby participants were invited to complete the PHQ-9 and GAD-7 every four weeks (Prestage et al., 2020).

Some implications arose from our analysis. Generally, the factors associated with increased anxiety and depression in our sample of GBM were ones that likely apply to all populations rather than being specific to GBM, such as those related to employment or loss of social contact. However, although it appeared from our data that COVID-19 did not detrimentally affect GBM to a greater extent than the general population, it is important to acknowledge that experiences of sexuality-related stigma and discrimination may impact GBM’s access to appropriate mental health services. Previous research has indicated that GBM have struggled to access sexuality-affirming and culturally safe mental health support (Waling et al., 2019). COVID-19 has highlighted why there is a critical need for generalist mental health support services to be culturally sensitive to diverse populations and where possible, indicate to prospective clients that their services are GBM-friendly. Such services should consider telehealth approaches to avoid disruptions to mental health care. Our finding that higher gay male-specific social engagement prior to COVID-19 was associated with increased depression has suggested that there may be an important role for lesbian, gay, bisexual, and transgender (LGBT) community organizations during periods of COVID-19
restrictions in providing online social support and community connection.

While a significant strength of our analysis was the capacity to compare the mental health of GBM during the first month of COVID-19 restrictions to previous mental health data in the same cohort, the analysis has some limitations. We used an online convenience sample and findings may not be representative of all GBM men in Australia; the sample was somewhat older than other typical samples of Australian GBM (Bavinton et al., 2020), was highly educated, and comprised mostly Australian-born men. The COVID-19 survey instrument itself may not have included all pertinent variables related to mental health among GBM, including quality of relationships and experiences of homophobia, given that the Flux Study is primarily focused on HIV prevention, sexual practices, and drug use. Measures related to experiences of COVID-19 were not validated, but due to the rapid onset of COVID-19 and the desire to implement rapid monitoring, this was unavoidable and likely affects most early COVID-19 research studies. Although a longitudinal study, we cannot be certain that COVID-19 caused changes in depression and anxiety, especially given that the pandemic occurred immediately after some months of bushfires that could also have impacted mental health for some Australians.

**Conclusion**

COVID-19, and the associated introduction of physical distancing restrictions in Australia, had a sudden and pronounced impact on the mental health of GBM, with increases in both depression and anxiety observed. Ongoing monitoring is required to determine the longer-term impacts, including to examine protective factors associated with resilience. While most factors associated with increased depression and anxiety were relatively general and not specific to GBM, given high baseline prevalence of mental health issues in this population, it is critical to ensure GBM have access to appropriate and sensitive supports as well as evidence-based interventions both during and after the COVID-19 pandemic.
