Abstract

Introduction: Thalassemia is a group of autosomal recessive inherited blood disorder characterized by reduced or no production of β-globin gene, leading to reduced synthesis of erythrocytes and anaemia. β-thalassemia is an autosomal recessive hereditary blood disorder in which there is reduced or no production of β-globin genes occurs, leading to decrease production of haemoglobin. It was originated and spread over Middle East, Mediterranean and Southeast Asia.

There are several treatment options for patients with β-thalassemia major but due to poor availability of medical care, safe and adequate transfusion of red blood cells, high cost and poor compliance with chelation therapy remains a challenging situation in developing countries. Treatment of β-thalassemia major is not considered easy due to severe complications in these patients including pericarditis, hypercoagulability, iron overload, hepatocellular carcinoma, osteoporosis and psychological problems. Traditional therapy in patients with β-thalassemia major includes supportive therapy by transfusion of red blood cells, iron chelation therapy to remove excessive amount of iron in the body, hydroxyurea therapy, erythropoietin etc. Despite of availability of various treatment options in β-thalassemia major, there are various complications being faced worldwide. Thalidomide was previously used to treat multiple myeloma. It has also significant role on HbF. Exact aetiology of its role is not known but it may be due to suppression of NF–κB induction caused by certain inflammatory cytokines including tumor necrotic factor–α (TNF–α), prostaglandin E2 synthesis (PG–E2), and vascular endothelial growth factor (VEGF), in association with increase in release of reactive oxygen species (ROS). Reactive oxygen species launches P38 MAPK, which causes increase in Hbf levels.

We analyzed the effect of thalidomide in patients with β–thalassemia major.

Materials and methods

It was a prospective study conducted at a tertiary care centre. 70 patients were included in this study. All patients were known cases of transfusion dependent β–thalassemia major. Study was performed from October 2017 to April 2018. Thalidomide was given at a dose of 2mg/kg to 10mg/kg for 6 months. Age, gender, haemoglobin levels, ferritin levels before and after therapy were assessed in all patients. A sample was taken in tube containing Gel for evaluation of serum ferritin. All data was collected and analyzed in SPSS 21.0.

Results

Among 70 patients, 46 were males and 24 were females (male to female ratio=1.9:1). Mean age of the patients was 10.31±1.24 years. Before and after treatment with thalidomide, all data were collected and analyzed in SPSS 21.0. P-value of <0.05 was considered as statistically significant.

Before treatment, haemoglobin levels ranged from 7.23 to 9.41g/dL, while after treatment with thalidomide, haemoglobin ranged from 8.93±1.04g/dL and 10.54±1.18g/dL respectively (p=0.011). Before and after treatment, mean serum ferritin level was 3125±143.51ng/mL and 1241±135.94ng/mL (p>0.001). Before and after treatment thalidomide.

Conclusion: Thalidomide proved to increased haemoglobin levels and reducing ferritin levels in patients with β-thalassemia major.

Effect of thalidomide in patients with β–thalassemia major

it ranged from 9.83 to 11.21 (mean=10.54±1.18g/dL) (Table 1 & 2) (Figure 2). There was statistically significant difference (p=0.011).

**Table 1** Evaluation of age, haemoglobin and serum ferritin levels before and after treatment (n=70)

|                  | Mean        | Standard Deviation |
|------------------|-------------|--------------------|
| Age              | 10.31       | 1.24               |
| Haemoglobin (g/dL) | Before treatment 8.93 | 1.04               |
|                  | After treatment 10.54 | 1.18               |
| Serum ferritin (ng/mL) | Before treatment 3125.24 | 143.51             |
|                  | After treatment 1241.85 | 135.94             |

Before treatment, serum ferritin was 2538 to 6429ng/mL (mean=3125±143.51ng/mL), while after treatment, it was 873 to 1582ng/mL (mean=135.94ng/mL) (Table 2 & 3) (Figure 3). The difference was statistically significant (p<0.001). Clinical features of patients are described (Table 3). All patients showed different transfusion frequencies (Table 4).

**Table 2** Difference in haemoglobin and ferritin levels before and after treatment (n=70)

|                  | Before Treatment | After Treatment | P–value |
|------------------|------------------|----------------|---------|
| Mean haemoglobin (g/dL) | 8.92±1.04       | 10.54±1.18    | 0.011   |
| Mean serum ferritin (ng/mL) | 3125.23±143.51 | 1241±135.94   | <0.001  |

Discussion

Thalassemia is a group of hereditary haemolytic anaemia caused by disruption in the production of haemoglobin chains. Various treatment options are available but the overall compliance, standardization and compliance is poor, due to which many complications develop in patients with thalassemia. Thalidomide is not commonly used in the patients with thalassemia as its role is not fully understood. In our study we evaluated the role of thalidomide to see its effect on haemoglobin and serum ferritin levels. It was found that mean haemoglobin levels was increased after treatment with thalidomide, while serum ferritin levels significantly decreases after treating with thalidomide. It is strongly suggestive of effect of thalidomide on HbF and also reduction in iron deposition.

Few studies are in favour of these findings. Fozza et al. presented 2 cases of non–transfusion dependant thalassemia. HbF was significantly raised in these patients after treatment with low–dose thalidomide. Ali et al. performed a study in 2016. He treated patients of β-thalassemia major with thalidomide and sodium butyrate. He strongly suggested that thalidomide was more efficient than sodium.
butyrate in expression of GATA–1 and EKLF genes, which efficiently induced the HbF levels in these patients. Ramanan et al. postulated the same evidence by treating patients with thalidomide. He proved that thalidomide significantly reduced ferritin levels in patients with β–thalassemia major. Masera et al. presented a case of patients with β–thalassemia major who was resistant to conventional therapy. Thalidomide proved the positive response by inducing HbF levels in the patient.

Various studies proved to be in favour of our study by showing similar results.

Conclusion

Thalidomide showed strongly positive results in patients with β–thalassemia major. Although our study was performed on fewer number of patients so more studies on large populations should be carried out to see strong findings and evidences. Our study did not evaluate the optimal transfusion interval in these patients as there was poor compliance and uneven follow-up of patients at the time of transfusion. Status of splenectomy was not included in this study, so further evaluation is needed in these patients on other parameters as well.
