We demonstrate the existence of stationary states composed of vortex lines attached to planar dark solitons in scalar Bose-Einstein condensates. Dynamically stable states of this type are found at low values of the chemical potential in channeled condensates, where the long-wavelength instability of dark solitons is prevented. In oblate, harmonic traps, U-shaped vortex lines attached by both ends to a single planar soliton are shown to be long-lived states. Our results are reported for parameters typical of current experiments, and open up a way to explore the interplay of different topological structures. These configurations provide Dirichlet boundary conditions for vortex lines and thereby mimic open strings attached to D-branes in string theory. We show that these similarities can be formally established by mapping the Gross-Pitaevskii theory into a dual effective string theory for open strings via a boson-vortex duality in 3+1 dimensions. Combining a one-form gauge field living on the soliton plane which couples to the endpoints of vortex lines and a two-form gauge field which couples to vortex lines, we obtain a gauge-invariant dual action of open vortex lines with their endpoints attached to dark solitons.

\section{I. INTRODUCTION}

Quantum vortices and planar dark solitons are frequently generated in current experiments with ultracold gases, from Bose-Einstein condensates (BECs) \cite{1, 2} to Fermi gases \cite{3, 4}. With phase imprinting techniques, the phase of the superfluid can be arranged to show either continuous $2\pi$ changes around vortex lines, or sudden leaps across the soliton planes. These topological defects, which separate regions with different values of the resulting order parameter, also appear after the quench crossing a second-order phase transition breaking the underlying continuous symmetry known as the Kibble-Zurek mechanism \cite{6, 7}. The great achievement of techniques in experiments with ultracold gases has directed researchers’ attention towards more complex physical systems presenting nontrivial topologies, which might simulate different types of topological excitations discussed in quantum field theory and string theory. For instance, analogues of cosmic strings in superfluids \cite{7, 8} and analogues of Dirac monopoles in the spin-1 BEC \cite{9, 10} have been proposed. He A-B interfaces and the boundary surface of the two-component BEC have been suggested as analogues of branes in string theory \cite{11–14}. Isolated monopoles \cite{15} and Dirac monopoles \cite{16} have been observed in recent spin-1 BEC experiments.

In this work we show that scalar BECs are also suitable for studying rich structures of topological defects. In spite of the fact that there have been an intensive research about vortices and solitons in scalar BECs, as far as we know, the study of topological structures showing junctions between them has not been performed. Only a particular configuration of this type has been addressed in the context of an effective low-dimensional model in trapped condensates \cite{17}. Note that in a trapped BEC without dark solitons stable vortex lines which do not form loops have to end at the condensate boundary. Here, within a mean field approach, we address the dynamics of scalar BECs containing vortex lines that extend between soliton stripes. This arrangement makes it possible to find the ends of a vortex line in the bulk of the system, just at the position of the soliton. Configurations of this type will be referred as open vortex lines, and they provide Dirichlet boundary conditions for the vortex ends. It is interesting to note that they mimic open strings attached to D-branes in string theory, in particular the so-called Bions. Although the arrangements shown in the present work are not generic from the string theory point of view, they might still offer a ground for simulating particular aspects of it. To establish this connection on more formal terms, we show that the Gross-Pitaevskii (GP) theory can be mapped into an effective string theory via the so-called boson-vortex duality.

The rest of the paper is structured as follows. In Section II, we present the mean field model based on the Gross-Pitaevskii energy functional, which is used to de-
scribe accurately the dynamics of BECs containing vortices and solitons. In Section III, we propose the boson-vortex duality for open vortex lines ending on dark solitons. The following sections are dedicated to particular realistic configurations fitting into both the GP description and its dual description. First, in Section IV, we consider condensates trapped along their transverse directions and containing axisymmetric vortex lines separated by dark solitons that extend over the cross section of the system. We demonstrate that a 3D condensate endowed with this structure can be a dynamically stable stationary state. Beyond a threshold value for the interaction energy such configuration becomes unstable due to the soliton decay, and the whole system can evolve through new emerging vortex lines. Second, in Section V, we study slightly oblate condensates holding symmetric planar solitons, to which U-shaped vortex lines, that are referred to as half vortex rings, are attached. In this variant configuration, each curved vortex line has both ends on a single dark soliton. We show that, although such stationary state is dynamically unstable, it has a long lifetime. The ultimate decay of the soliton shows chaotic behaviors of vortex lines, which might be related to quantum turbulence processes. A common feature of both configurations is the presence of vortex line pairs separated by the soliton plane. We finish with the conclusions in Section VI, where we emphasize that the topological states considered in this paper are feasible to be realized under current experimental techniques.

II. GROSS-PITAЕVSKII MODEL

We follow a mean-field approach for modeling dilute gases of repulsive interacting bosons making Bose-Einstein condensates at zero temperature. The state of such a system is described by a complex order parameter \( \Psi(r,t) \), whose dynamics is determined by the non-relativistic GP Lagrangian density:

\[
\mathcal{L}_{\text{GP}} = \frac{i\hbar}{2} \left( \frac{\Psi^*}{\partial t} - \frac{\partial \Psi}{\partial t} \right) - H_{\text{GP}},
\]

where the energy density is given by

\[
H_{\text{GP}} = \frac{\hbar^2}{2m} |\nabla \Psi|^2 + \frac{g}{2} (|\Psi|^2 - |\Psi_0|^2)^2.
\]

Here \( g = 4\pi \hbar^2 a/m \) is the interaction parameter, characterized by the s-wave scattering length \( a \) and the atomic mass \( m \). Note that the energy is measured relative to the ground state \( \Psi_0(r,t) = \psi_0(r) \exp(-i\mu t/\hbar) \) with chemical potential \( \mu \). For homogeneous systems, \( \Psi_0 \) is a real constant, apart from a global phase, and \( \mu \) fixes the value of the uniform density \( |\Psi_0|^2 = \mu/g \). In the presence of an external potential \( V(r) \), a local chemical potential \( \mu_l(r) = \mu - V(r) \) can be defined, which in the limit of high interaction energy, or Thomas-Fermi regime, allows to approximate the non-uniform ground-state density by \( |\Psi_0(r)|^2 = \mu_l(r)/g \). In this way, we will use Eq. (1) as a unified model for both homogeneous and non-homogeneous systems. In the latter case, this means that when the system is closed, the energy is measured with respect to the ground state having the same chemical potential, and thus, in general, a different number of particles. For non-homogeneous systems, we will consider harmonic trapping potentials with cylindrical symmetry \( V(r) = V_z(z) + V_{\perp}(r_{\perp}) = m\omega_{\perp}^2 r_{\perp}^2 / 2 + m\omega_z^2 z^2 / 2 \), having an aspect ratio \( \lambda = \omega_z/\omega_{\perp} \), where the transverse coordinates are \((\theta, r_{\perp}) = (\tan^{-1}(y/x), \sqrt{x^2 + y^2}) \). As a length unit, we define the characteristic length of the transverse trap \( a_{\perp} = \sqrt{\hbar/\pi \omega_{\perp}} \).

The equation of motion corresponding to the Lagrangian density \( \mathcal{L}_{\text{GP}} \) is the time-dependent GP equation

\[
i\hbar \frac{\partial \Psi}{\partial t} = \left( -\frac{\hbar^2}{2m} \nabla^2 + g(|\Psi|^2 - |\Psi_0|^2) \right) \Psi.
\]

Its stationary solutions with chemical potential \( \mu \), that is \( \Psi(r,t) = \psi(z,\theta, r_{\perp}) \), fulfill the time-independent GP equation

\[
\left( -\frac{\hbar^2}{2m} \nabla^2 + g(|\psi|^2 - |\psi_0|^2) \right) \psi = 0.
\]

III. DUALITY

A. Effective string action

The boson-vortex duality is a powerful tool to study the dynamics of vortex rings [18–22]. It has been demonstrated that the dual description of the GP theory in 3+1 dimensions is equivalent to a certain type of effective string theory [19, 20, 23]. In this paper we extend the dual mapping to open vortex lines and argue that dark solitons in the original GP theory could play the role of D-branes in the effective string theory by introducing a pinned boundary condition for vortex lines [24]. In the following, for simplicity we set the trapping potential to be zero, i.e. \( V(r) = 0 \).

Introducing the Madelung transformation \( \Psi = \sqrt{\rho} e^{i\phi} \), the equivalent expression of the GP Lagrangian density Eq. (1) in terms of the condensate density \( \rho \) and the phase \( \phi \) reads

\[
\mathcal{L}_{\text{GP}} \simeq -\hbar \rho \dot{\phi} - \rho \frac{\hbar^2}{2m} (\nabla \phi)^2 - \frac{g}{2} (\rho - \rho_0)^2,
\]

where we neglect the quantum pressure term \( \sim (\nabla \sqrt{\rho})^2 \), which should be valid at long wavelengths (the hydrodynamic limit) that we are interested in. We rewrite the quadratic term \( -\rho \hbar^2 (\nabla \phi)^2/2m \) via the so-called Hubbard-Stratanovich transformation [25], and obtain the dual representation of the original theory Eq. (5) :

\[
\mathcal{L}_{\text{GP}} \simeq -\hbar \rho \dot{\phi} - \hbar \nabla \phi \cdot \mathbf{f} + \frac{m}{2\rho} \mathbf{f} \cdot \mathbf{f} - \frac{g}{2} (\rho - \rho_0)^2
\]

\[
= -\hbar \rho \mu \partial_\mu \phi + \frac{m}{2\rho} \mathbf{f} \cdot \mathbf{f} - \frac{g}{2} (\rho - \rho_0)^2,
\]

where \( \mathbf{f} \) is the fermion field, \( \mu \) is the chemical potential, and \( \rho_0 \) is the density at the center of the trap.
where \( \partial_\mu \equiv (\partial_\mu, \nabla) \), and \( f \) is an auxiliary three-vector, which is also the space-like components of the four-vector \( f^\mu \equiv (\rho, \bf{f}) \). The physical meaning of the field \( f \) becomes clear by evaluating its equation of motion \( f = \rho \frac{\hbar}{m} \nabla \phi \), which matches the superfluid current \( J \) in the GP theory described by Eq. (1) [18].

Let us now decompose the phase \( \phi \) into a non-singular part and a few singular parts related to the topological defects:

\[
\phi = \phi_g + \phi_{cv} + \phi_{ov} + \phi_s,
\]

where \( \phi_g \) is the smooth phase, which is the Goldstone mode associated with the \( U(1) \) symmetry breaking, \( \phi_{cv} \) is the phase of vortex rings, \( \phi_{ov} \) is the phase of open vortex lines, and \( \phi_s \) represents the phase of dark solitons. Note that Eq. (7) just means that \( \phi_{cv}, \phi_{ov} \) and \( \phi_s \) have singularities, and they may still contain smooth parts. The action of the non-singular part \( \phi_g \) reads

\[
S_g = \int d^4x \left( -\hbar f^\mu \partial_\mu \phi_g \right) = \hbar \int d^4x \left[ \partial_\mu f^\mu \phi_g - \partial_\mu (f^\mu \phi_g) \right].
\]

By integrating out the smooth phase \( \phi_g \) in the bulk, we obtain

\[
\partial_\mu \rho + \nabla \cdot \bf{f} = \partial_\mu f^\mu = 0,
\]

which can be solved by

\[
f^\mu = \frac{1}{2} \epsilon^{\mu\nu\lambda\sigma} \partial_\nu B_{\lambda\sigma},
\]

where \( \epsilon^{\mu\nu\lambda\sigma} \) is the totally-antisymmetric tensor, and \( B_{\lambda\sigma} \) is an antisymmetric rank-2 gauge field. Note that \( f^\mu \) is invariant under the gauge transformation \( B_{\mu\nu} \rightarrow B_{\mu\nu} + \partial_\mu \Lambda_\nu - \partial_\nu \Lambda_\mu \), where \( \Lambda_\nu \) is an arbitrary four vector.

In the dual description, the action of a vortex ring in \( 3+1 \) dimensions has already been proposed [18–20, 23]. In this paper we focus on open vortex lines. For an open vortex line the action reads

\[
S_{ov} = \int d^4x \left( -\hbar f^\mu \partial_\mu \phi_{ov} \right) = \hbar \int d^4x \left[ \partial_\mu (\epsilon^{\mu\nu\lambda\sigma} B_{\lambda\sigma} \partial_\nu \phi_{ov}) - B_{\mu\nu} \epsilon^{\mu\nu\lambda\sigma} \partial_\lambda \partial_\sigma \phi_{ov} \right].
\]

We elaborate on these terms by considering a vortex line which is parallel to the z-axis, whose topological nature can be seen from the term

\[
\int d^2x \epsilon^{z\lambda\sigma} \partial_\lambda \partial_\sigma \phi_{ov} = 2\pi.
\]

The topological defects produced by vortex lines can be introduced explicitly through

\[
\epsilon^{\mu\nu\lambda\sigma} \partial_\lambda \partial_\sigma \phi_{ov} = -2\pi \sum_i \int d\tau d\sigma \epsilon^{\alpha\beta} \partial_\alpha X^\mu \partial_\beta X^\nu \delta^4(x^\mu - X^\mu),
\]

where \( \Sigma_i \) is the worldsheet spanned by the \( i \)-th vortex line, and \( \alpha, \beta \in \{0, 1, \} \) label the worldsheet coordinates. \( \epsilon^{\alpha\beta} \) is a rank-2 antisymmetric tensor, and we set \( \epsilon^{10} = 1 \).

The space \( \sigma \in [\sigma_0, \sigma_1] \), and the time \( \tau \) is chosen to be \( t \). \( X^\mu = X^\mu(\tau, \sigma) \) stands for the coordinates of a vortex line, namely \( X^0 = t, \mathbf{X} = (x, y, z) \). Hence, the bulk action of the open vortex line reads

\[
S_{bulk}^\nu = -\frac{\hbar}{2} \int d^4x B_{\mu\nu} \epsilon^{\mu\nu\lambda\sigma} \partial_\lambda \partial_\sigma \phi_{ov} = \frac{\eta}{2} \sum_i \int_{\Sigma_i} d\tau d\sigma B_{\mu\nu} \epsilon^{\alpha\beta} \partial_\alpha X^\mu \partial_\beta X^\nu,
\]

where \( \eta = 2\pi \hbar \) and \( B_{\mu\nu} = B_{\mu\nu}(X^\nu) \).

Suppose that an \( (x,y) \)-planar dark soliton, to which a vortex line can be attached, is located at \( z = z_0 \). We make use of the soliton property of producing a localized \( \pi \) phase jump by crossing the soliton plane, i.e.

\[
\partial_z \phi_s(t, x, y, z) = \pi \int d^3\sigma \delta^3(x^a - Y^a(\sigma_i)) \delta(z - z_0),
\]

where \( \sigma_i \) are the coordinates on the dark soliton plane, \( Y^a(\sigma_i) \) is the map from \( \sigma_i \) to the spacetime coordinates, \( \ell \) is a length scale inserted for dimensional reasons, and \( \phi_s(\sigma_i) \) is the transverse phase defined only along the dark soliton plane, which in turn contains a smooth part and a singular part. In addition, the superfluid current along the \( z \)-direction vanishes at the soliton plane

\[
J^z(t, x, y, z_0) = 0,
\]

which implies \( f^z(t, x, y, z_0) = 0 \) and thus imposes a constraint on the B-field, according to Eq. (10). Consequently, the boundary term in the action Eq. (8) vanishes on the dark soliton surface

\[
S_s = \int d^4x \left( -\hbar f^\mu \partial_\mu \phi_s \right) = -\hbar \int d^3x \left( \ell f^a \partial_a \phi_s \right).
\]

Combining the boundary term in the action of the open vortex Eq. (11):

\[
\frac{\hbar}{2} \int d^3x \epsilon^{abc} B_{bc} \partial_a \phi_{ov} ,
\]

with \( a,b,c \in \{t, x, y\} \), and the dark soliton action Eq. (17), we obtain the boundary action

\[
S_{boundary} = -\hbar \int d^3x \left( \ell f^a - \frac{1}{2} \epsilon^{abc} B_{bc} \right) \partial_a \phi_s.
\]

Here we made the identification \( \phi_{ov}(z \rightarrow z^+_0, x, y, t) = \phi_s(x, y, t) \), which implies that the endpoints of the open
vortex lines are the vortex excitations living on the soliton surface \((z \to \pm \rho_0)\). As it has previously been done for \(\phi_g\), integrating out the smooth part of \(\tilde{\phi}_s\) leads to
\[
\partial_a (\ell f^a - \frac{1}{2} \epsilon^{abc} B_{bc}) = 0 , \tag{20}
\]
whose solution is
\[
f^a - \frac{1}{2} \epsilon^{abc} B_{bc} = \frac{1}{2} \epsilon^{abc} F_{bc} , \tag{21}
\]
where \(F_{ab} = \partial_a A_b - \partial_b A_a\) is the field strength of \(A_a\), and \(A_a\) is a one-form gauge field living on the dark soliton surface \((z \to \pm \rho_0)\). Therefore, we are left with the singular part \(\tilde{\phi}_s^a\) of \(\phi_s\)
\[
S_{\text{boundary}} = -\hbar \int d^2 x \frac{1}{2} \epsilon^{abc} F_{bc} \partial_a \tilde{\phi}_s^a
\]
\[
= -\frac{1}{2} \hbar \int d^3 x \epsilon^{abc} (\partial_a A_c - \partial_c A_a) \partial_a \tilde{\phi}_s^a
\]
\[
= -\frac{1}{2} \hbar \int d^3 x A_a (\epsilon^{abc} \partial_b \partial_c \tilde{\phi}_s^a) , \tag{22}
\]
and for the endpoints of vortex lines, similar to Eqs. (12)–(13), we get
\[
\epsilon^{abc} \partial_b \partial_c \tilde{\phi}_s^a = -2 \pi \sum_i \int_{\partial \Sigma_i} d\tau \partial_\tau X^a (x - X^a(\tau)) , \tag{23}
\]
where \(\partial \Sigma_i\) is the boundary of the worldsheet \(\Sigma_i\), and \(X^a(\tau)\) are the coordinates of an endpoint of a vortex line, namely \(X^0 = t\), \(X = (x, y)\). Then we obtain
\[
S_{\text{boundary}} = -\hbar \int d^2 x A_a (\epsilon^{abc} \partial_b \partial_c \tilde{\phi}_s^a)
\]
\[
= \eta \sum_i \int_{\partial \Sigma_i} d\tau A_a \partial_\tau X^a , \tag{24}
\]
where \(A^a = A^a(X^a)\).

In terms of the field strengths, the last two terms of the action Eq. (6) can be written as
\[
S_{\text{gauge}} = \frac{m}{2 \rho} f \cdot f - \frac{g}{2} (\rho - \rho_0)^2
\]
\[
- \frac{g}{4 \ell} \int d^3 x (\bar{F} + \bar{B})^2 - \frac{g}{2} \int d^4 x \ h_3^2 . \tag{25}
\]
Near \(\rho \approx \rho_0\), \(H_{\mu \nu \lambda} \approx \partial_{\mu} B_{\nu \lambda} + \partial_{\nu} B_{\mu \lambda} + \partial_{\lambda} B_{\mu \nu} \approx H_{\mu \nu \lambda}^0 + h_{\mu \nu \lambda}\), where \(H_{\mu \nu \lambda}^0\) is the background field with \(H_{123}^0 = 0\), and the fluctuations are given by \(h_{3}^2 = h_{\mu \nu \lambda} h_{\mu \nu \lambda}/6\), through the metric \(\eta_{\mu \nu} = \text{diag}\{-c_s^2, 1, 1\}\) determined by the speed of sound \(c_s = \sqrt{gp_0/m}\). \(\bar{F}\) and \(\bar{B}\) are the fluctuations of \(F\) and \(B\) on the soliton plane respectively.

Collecting all the contributions, we finally obtain the following dual description of open vortex lines:
\[
S^* = S_{\text{bulk}}^* + S_{\text{boundary}}^* + S_{\text{gauge}}^*
= \frac{\eta}{2} \sum_i \int_{\Sigma_i} d\tau \partial_\tau X^a \partial_\tau X^a - \frac{g}{4 \ell} \int d^3 x (\bar{F} + \bar{B})^2
+ \eta \sum_j \int_{\partial \Sigma_j} d\tau A_a \partial_\tau X^a - \frac{g}{4 \ell} \int d^3 x \ h_3^2 . \tag{26}
\]

The summation over \(\Sigma_i\) includes all the vortex lines and the summation over \(\partial \Sigma_j\) includes all the endpoints of vortex lines attached to dark solitons. It is important to note that the resulting action Eq. (26) is invariant under the gauge transformations [26]:
\[
B_{\mu \nu} \rightarrow B_{\mu \nu} + \partial_\mu \Lambda_\nu - \partial_\nu \Lambda_\mu ,
\]
\[
A_a \rightarrow A_a - \Lambda_a . \tag{27}
\]

The action given in Eq. (26) has two aspects. First of all, it provides a hydrodynamic description of open vortex lines in scalar BECs, which is useful to study the dynamics of open vortex lines with Dirichlet boundary conditions and vortex-sound interactions. On the other hand, it can be viewed as an effective open string action without the tension term, or equivalently an action in the large \(B\)-field limit, in the presence of D-branes. Hence, the dual theory Eq. (26) might provide a possibility to test some aspects of string theory in BEC experiments.

### B. Equation of motion

In the following we will discuss a simple example of the action Eq. (26). From now on we will only consider a single vortex line whose endpoints are attached to two parallel dark solitons. Here, for simplicity, we ignore the dynamics of the dark solitons and treat them as hard walls. We will also assume that the fluctuations of \(B_{\mu \nu}\) and \(A_a\) in space-time are small, and hence the field strength parts in \(S_{\text{gauge}}^*\) can be neglected since they provide higher order terms.

In order to have non-trivial dynamics of a single vortex line, we need to introduce in the action Eq. (26) a phenomenological tension term, which plays the role of kinetic energy of vortices. This term has been neglected up to now because of the assumption of infinitely thin topological defects. Such assumption implies the lack of vortex cores and also the absence of a “physical” mass of the vortex lines, which is responsible, among other dynamical effects, for the buoyancy-like forces in inhomogeneous backgrounds [27]. As a consequence, the tension term can be seen as a remnant of the core structure of the vortices in the hydrodynamic limit.

We introduce the tension term in Eq. (26) by adding a Polyakov string action [26] proportional to the string
tension $T$:
\[
S_{\text{single}} = \frac{T}{2c_s} \int \sum d\sigma d\tau \sqrt{-h} h^{\alpha\beta} \eta_{\mu\nu} \partial_\alpha X^\mu \partial_\beta X^\nu \\
+ \eta \frac{1}{2} \int \sum d\sigma d\tau B_{\mu\nu} \epsilon^{\alpha\beta} \partial_\alpha X^\mu \partial_\beta X^\nu \\
+ \eta \int \sum d\tau A_\alpha \partial_\tau X^\alpha , \tag{29}
\]
where $h^{\alpha\beta} = \text{diag}(-1/c_s^2,1)$ is the worldsheet metric, and $\sqrt{-h} = \sqrt{-\text{det}(h_{\alpha\beta})} = c_s$. $T$ has the standard dimension $[E]/[L]$ for the string tension and in terms of BEC units $T \sim \pi \hbar^2 \rho_0/2m$.

Considering a small variation $\delta X^\mu$ on top of the background vortex configuration $X^\mu$ [28], the variation of the action to the leading order in $\delta X^\mu$ reads
\[
\delta S_{\text{single}} = \frac{T}{2} \int \sum d\sigma d\tau 2 \partial_\alpha (\delta X^\mu) \partial^\alpha X^\mu \\
+ \eta \frac{1}{2} \int \sum d\sigma d\tau B_{\mu\nu} \epsilon^{\alpha\beta} (\partial_\alpha \delta X^\mu) \partial_\beta X^\nu \\
+ \eta \frac{1}{2} \int \sum d\sigma d\tau B_{\mu\nu} \epsilon^{\alpha\beta} (\partial_\alpha X^\mu) (\partial_\beta \delta X^\nu) \\
+ \eta \frac{1}{2} \int \sum d\sigma d\tau (\partial_\alpha B_{\mu\nu}) (\delta X^\nu) \epsilon^{\alpha\beta} \partial_\alpha X^\mu \partial_\beta X^\nu \\
+ \eta \int \sum d\tau (\partial_\alpha A_\alpha) (\delta X^\mu) \partial_\tau X^\alpha \\
+ \eta \int \sum d\tau A_\alpha \partial_\tau (\delta X^\alpha) \\
= -T \int \sum d\sigma d\tau (\delta X^\mu) \partial^\alpha \partial_\alpha X^\mu \\
+ \eta \frac{1}{2} \int \sum d\sigma d\tau H_{\mu\lambda\nu} (\delta X^\mu) \epsilon^{\alpha\beta} \partial_\alpha X^\lambda \partial_\beta X^\nu \\
+ T \int \sum d\tau (\delta X^\alpha) \partial_\sigma X_\alpha \\
+ \eta \int \sum d\tau (B_{ab} + F_{ab}) (\delta X^a) \partial_\tau X^b . \tag{30}
\]

Hence the equation of motion of the vortex line in the bulk is given by
\[
-T \partial_\alpha \partial^\alpha X^\mu + \eta \frac{1}{2} \epsilon^{\alpha\beta} H_{\mu\lambda\nu} \partial_\alpha X^\lambda \partial_\beta X^\nu = 0 , \tag{31}
\]
and the dynamics of the endpoints reads
\[
T \partial_\sigma X_\alpha \big|_{\sigma_1} + \eta (B_{ab} + F_{ab}) \partial_\tau X^b \big|_{\sigma_1} = 0 \tag{32}
\]
and
\[
-T \partial_\sigma X_\alpha \big|_{\sigma_0} - \eta (B_{ab} + F_{ab}) \partial_\tau X^b \big|_{\sigma_0} = 0 . \tag{33}
\]

We now consider a special situation. In the bulk $H_{ij} = 0$, and $H_{ijk} = \rho_0 \epsilon_{ijk}$. On the boundaries $A_0 = 0$, $\partial_\tau A_\alpha(\sigma_1) = \partial_\tau A_\alpha(\sigma_0) = 0$ and $B_{nm}(\sigma_1) = B_{nm}(\sigma_0) = \rho_0 \epsilon_{nm}$. Here $m, n = 1, 2$. For this special case we obtain the following equations
\[
0 = T \left( \frac{\partial^2 X^\mu}{\partial \sigma^2} - \frac{1}{c_s^2} \frac{\partial^2 X_1}{\partial \tau^2} \right) - \frac{\eta}{2} \epsilon^{\alpha\beta} \rho_0 \epsilon_{ijk} \partial_\alpha X^j \partial_\beta X^k , \\
0 = T \partial_\sigma X_n + \eta \rho_0 \epsilon_{nm} \partial_\tau X^m . \tag{34}
\]

Here we only look for a static solution. For a static vortex line,
\[
\frac{\partial^2 X_1}{\partial \sigma^2} = 0, \quad \partial_\tau X_n = 0 . \tag{35}
\]
The general solution would be
\[
x = a_1 \sigma + a_2 , \quad y = b_1 \sigma + b_2 , \quad z = c_1 \sigma + c_2 , \tag{36}
\]
where $a_1, a_2, b_1, b_2, c_1$ and $c_2$ are constants. By choosing the proper coordinates and taking into account the boundary conditions, the static solution reads
\[
x = a_2 , \quad y = b_2 , \quad z(\sigma) = c_1 \sigma + c_2 , \tag{37}
\]
which describes a static open vortex line between two dark solitons. Note that this vortex line satisfies Neumann boundary conditions along $x$ and $y$ directions, while fulfills Dirichlet boundary condition along $z$ direction. If we replace the current boundary conditions with periodic boundary conditions, Eq. (35) would give a trivial solution, which means that vortex rings must propagate as it is well-known.

In the next two sections we show that such static vortex-soliton composite topological excitations can indeed be found in the GP theory. For the sake of comparison with realistic parameters used in current experiments of ultracold gases, in what follows we report numerical results for systems composed of $^{87}$Rb atoms, with scattering length $a = 5.29$ nm, confined by harmonic potentials with angular frequencies in the range $2\pi \times [10 – 100]$ Hz.

## IV. OPEN VORTEX LINES

### A. Configurations

In this section, we consider elongated condensates along the axial $z$-direction (assuming $\omega_z = 0$) and isotropic trapping in the transverse plane, providing the system with a channeled structure. In particular, we will consider stationary states containing vortex lines attached to solitons. The simplest configuration of this type, containing a single dark soliton, is shown in Fig. 1. In order to realize this simple configuration we have devised a channeled, cylindrical geometry with an axismetric vortex line:
\[
\psi(z, \theta, r_\perp) = \psi_1(z, r_\perp) e^{i\theta} , \tag{38}
\]
where $\psi_1(z, r_\perp)$ is a real function. After substituting in Eq. (4), the vortex solution gives
\[
-\frac{\hbar^2}{2m} \left( \partial_\tau^2 + \nabla_\perp^2 - \frac{1}{r_\perp^2} \right) \psi_1 + V_\perp \psi_1 + g |\psi_1|^2 \psi_1 = \mu \psi_1 , \tag{39}
\]
where $\nabla_{\perp}^2 = \partial^2_{r_{\perp}} + \partial^2_{\theta_{\perp}}/r_{\perp}$ and $V_{\perp}$ accounts for the transverse confinement. This is the stationary equation for a vortex state that generates a tangential velocity field $v = \hbar \nabla \arg(\psi)/m$ around the $z$-axis: $v(r_{\perp}) = \hbar u_0/mr_{\perp}$, where $u_0$ is the unit tangent vector.

Next, we search for solutions to the nonlinear Eq. (39) including a dark soliton along the axial direction. An analytical ansatz for this configuration is

$$\psi_1(z, r_{\perp}) = r_{\perp} \chi(r_{\perp}) \tanh \left( \frac{z}{\xi(r_{\perp})} \right), \quad (40)$$

where $\xi(r_{\perp}) = \hbar/\sqrt{mg|\chi(r_{\perp})|^2}$ defines a radius-varying healing length through the Thomas-Fermi density profile $|\chi(r_{\perp})|^2 = \mu_0(r_{\perp})/g$ of a system without the vortex. This expression follows the ansatz introduced in Ref. [29] for 3D dark solitons in channeled condensates, and gives a good estimate in the strongly interacting regime, where the Thomas-Fermi approximation applies. Although the $r_{\perp}$ factor of Eq. (40) accounts for the vortex core in a quite simple manner, which is characteristic of the corresponding noninteracting system, it will turn out to be efficient in getting numerical convergence to the real stationary state.

By using the ansatz Eq. (40) for open vortex lines, we have followed a Newton method to find the exact numerical solution to the full GP Eq. (4). Fig. 1 shows the features of this configuration (without axial confinement) around a vortex-soliton junction, which leads to Dirichlet boundary conditions for the vortex end points. The panel Fig. 1(a), presenting a semi-transparent density isocontour of the condensate at 5% of maximum density, shows how the presence of the dark soliton breaks the system into two phase-separated subsets containing corresponding axisymmetric vortices. These vortices are different entities, as can be seen in the detailed view of panel Fig. 1(b). The dark soliton twists their relative phase in $\pi$ radians along the $z$-axis for every value of the azimuthal coordinate $\theta$, and their end points lay aligned on opposite sides of the soliton membrane. Characteristic features of the system are depicted in Fig. 1(b)-(c): the axial phase jump for a given azimuthal angle, and the axial density of the condensate after integration over the transverse coordinates $n_1(z) = \int |\psi(z, r_{\perp}, \theta)|^2 r_{\perp} \, dr_{\perp} \, d\theta$ times the scattering length. The stability of this and more complex configurations within the GP theory will be analyzed in Sections IV-V in realistic condensates.

It is important to note that for scalar BECs, a hypothetical configuration with a single vortex line attached to a dark soliton is not stationary. For such a case, the phase difference between the left and the right side of the dark soliton changes continuously along the azimuthal angle from 0 to $\pi$. As a consequence, the superfluid density can not be zero all along the soliton plane, and the superfluid velocity is non-uniform, which makes this a transient configuration.

It is also interesting to consider configurations containing two nearby dark solitons, as the one presented in Fig. 2 for a condensate having $\mu = 4 \hbar \omega_{\perp}$. In this arrangement, the interaction between solitons is mediated in the long range by the vortex lines. Fig. 2(a) shows the isocontour at 5% of maximum density colored according to the complex phase pattern produced by the interplay of solitons and vortices. As can be deduced from Fig. 2(b)-(c), presenting the axial phase and density of the system, the inner region between solitons is characterized by a state that differs in the phase from that of the outer region.

### B. Stability

States containing open vortex lines, as exemplified by Figs. 1 and 2, are dynamically stable as long as the dark soliton does not decay. As it is known, the decay of multidimensional dark solitons is produced by long-wavelength modes excited on the soliton membrane, through the so-called snaking instability [30]. However, such modes can be prevented to appear by means of a tight transverse...
be done through the Bogoliubov equations (BE) for the linear excitations of the condensate. To this aim, we introduce the linear modes \( \{u(r), v(r)\} \) with energy \( \mu \pm \hbar \omega \) to perturb the equilibrium state, i.e. \( \Psi(r,t) = \psi + \sum_q (u e^{-i \omega q t} + v^* e^{i \omega q t}) \). After substitution in Eq. (3), and keeping terms up to first order in the perturbation, we get

\[
(H_L + 2g|\psi|^2) u + g\psi^2 v = \hbar \omega u, \quad (41a) \\
-g(\psi^*)^2 u - (H_L + 2g|\psi|^2) v = \hbar \omega v, \quad (41b)
\]

where \( H_L \) is the linear part of the Hamiltonian in Eq. (3), i.e. \( H_L = -\hbar^2 \nabla^2/2m + V(r) - \mu \). These equations allow to identify the dynamical instabilities of the stationary state \( \psi \), which are associated to the existence of \( \omega \) frequencies with non-vanishing imaginary parts.

For the vortex state \( \psi(z, \theta, r_\perp) = \psi_1(z, r_\perp) e^{i \theta} \) the BE Eq. (41) read

\[
(H_L + 2g\psi^2_1) u + g\psi^2_1 e^{i2\theta} v = \hbar \omega u, \quad (42a) \\
-g\psi^1_1 e^{-i2\theta} u - (H_L + 2g\psi^2_1) v = \hbar \omega v, \quad (42b)
\]

We search for the modes of the functional form \( \{u(z, r_\perp) e^{i(q+1)\theta}, v(z, r_\perp) e^{i(q-1)\theta}\} \) with \( q = 0, \pm 1, \pm 2, \ldots \)
modes in the condensate, which can produce the decay of the dark soliton. Following a procedure parallel to that used in Ref. [29], based in a separable ansatz for \( f_{\pm} \) within the Thomas-Fermi regime, the bifurcation points for \( q = 0 \) can be estimated to appear at chemical potential values \( \mu_0 = \sqrt{2} (2p + 2) h \omega_\perp \), where \( p = 1, 2, \ldots \) is a radial quantum number. The pair \((p, q)\) characterizes the corresponding transverse unstable modes localized at the soliton plane, and indicates the number of radial and azimuthal nodal points, respectively. Specifically, for \((p = 1, q = 0)\) the predicted unstable mode will appear at \( \mu = 5.66 h \omega_\perp \), which is close to the value \((\approx 5)\) found by numerically solving Eq. (43).

The upper panel of Fig. 3 shows the numerical solutions to Eq. (43) for the unstable excitation frequencies of open-vortex-line states. As can be seen, the unstable modes with \( q = 1, 2 \) \((p = 0)\) appear before those with \( q = 0 \). The latter excitations introduce radial nodes \((p \neq 0)\) in the soliton plane, whose energy cost is higher than the kinetic energy excess \((\propto h^2 q^2 / 2m)\) of the azimuthal nodes generated by the modes with \( q = 1, 2 \). In particular, for a computational domain with periodic boundary conditions and axial length \( 4π a_\perp \), the excitation of transverse modes with \( q = 1 \) above \( \mu = 3.0 h \omega_\perp \) marks the threshold for instability. As previously commented, the small bump extended between 3.05 \( h \omega_\perp \) and 3.4 \( h \omega_\perp \) on the \( \mu \) axis is due to small instabilities derived from the vortex–soliton junction, and are represented by the \((q = 1)\)–dashed line of Figure 3. To illustrate this point, the lower panel of Fig. 3 depicts the density isocontours of an open vortex state with \( \mu = 3.2 h \omega_\perp \) (semi-transparent contour) and its only unstable modes coming from the vortex–soliton junction (colored contours). Such unstable modes are not exclusively localized around the junction. This specific instability ceases to act for an intermediate range of chemical potentials, where the snaking instability makes its appearance through the \( q = 1 \) solid curve.

We have cross-checked our results obtained from the linear stability analysis, by evolving in real time the stationary states \( \psi \) with different chemical potentials, after adding a random Gaussian perturbation \( \psi \rightarrow \psi + \delta \psi \). The upper panel of Fig. 4 presents an example of such dynamics for a condensate with \( \mu = 3 \ h \omega_\perp \), just below the instability threshold. The system remains nearly unaltered during the whole evolution, thus stable according to the linear analysis of Fig. 3; only smooth oscillations due to sound waves can be observed.

For states with two solitons, as shown in Fig. 2, whenever the distance between solitons is large in comparison with the healing length, the stability analysis follows that of a single soliton. To illustrate their characteristic dynamics, we have selected an unstable system with \( \mu = 5.1 h \omega_\perp \), shown in the lower panel of Fig. 4. As can be seen, at about 20 ms, the snaking instability starts to operate at the planes of the solitons, while the vortices begin to lose their alignment. At later time, two new vortices appear as a remainder of the two initial solitons.
FIG. 5. Half vortex rings attached to a dark soliton in an oblate condensate with \( \mu = 6 \hbar \omega_z \) confined by a harmonic trap with aspect ratio \( \lambda = 1.4 \). Density isocontours at 5% of maximum density are shown for the semi-transparent top and side views (left panels) and the perspective view colored by phase (top right). (d) Column density profile along the \( z \)-axis.

along with manifest oscillations of the initial straight axisymmetric vortices.

V. HALF VORTEX RING STATES

In this section we consider a variant layout with curved open vortex lines having both ends attached to the same planar dark soliton. The resulting structures bear some resemblance to the U-shaped vortices found in elongated systems [33], where the vortex lines bend near their end points. On the contrary, here we focus on half vortex rings. These objects have been studied in the realm of classical fluids [34], and can propagate long distances attached to the water surface without decaying (see for instance [35], where they are shown to provide the mechanism of motion for light insects). This configuration mimics an open string whose both ends are attached to the same D-brane, which is another basic configuration of an open string.

In order to generate half vortex rings in a BEC, we proceed with two steps. We first search for stable vortex rings, which are later split into two halves by imprinting a planar dark soliton. To this end, we have chosen near-spherical, harmonically trapped condensates, where the conditions for the stability of vortex rings have been analytically predicted for aspect ratios in the range \( 1 \leq \lambda \leq 2 \) within the strongly interacting regime [36], and have been numerically corroborated in some particular cases near the weakly interacting regime [37]. Our results show that the analytical prediction breaks down for small values of the chemical potential, where, on the other hand, the conditions for the stability of solitons can be expected. As a result, we have not found a stable half vortex ring, although it is possible to observe robust configurations with weak instabilities. This is the case presented in Fig. 5, corresponding to the aspect ratio \( \lambda = 1.4 \) and the chemical potential \( \mu = 6 \hbar \omega_z \). The translucent density isocontours Fig. 5(a)-(b) show the condensate from two perpendicular views, and the colored density isocontour Fig. 5(c) reproduces the resulting phase pattern from the interplay between the soliton (lying across the \( x \)-coordinate) and the vortices. By integration of the density over the \( x \)-coordinate [panel Fig. 5(d)], it is possible to observe the density depletion produced by the vortices at \( z = 0 \). As demonstrated in Fig. 6(a), showing the real time evolution of this state obtained from the numerical solution of the full GP equation (3), the half vortex ring is a robust state, which is able to survive under perturbations during 100 ms in a harmonic trap with \( \omega_z / 2\pi = 11.5 \) Hz.

Other choices of parameters can lead to different lifetimes for half vortex rings. As an alternative example, in Fig. 6(b) we present a near-spherical condensate with \( \lambda = 1.1 \) and a higher chemical potential \( \mu = 8.9 \hbar \omega_z \), in a trap with \( \omega_z / 2\pi = 57.5 \) Hz. In this case, the dark soliton decay begins around 10 ms, and the later evolution shows complex dynamics. As a general trend, for high values of \( \mu \) we have observed a chaotic scenario at the later stages of the half-vortex-ring decay, including the appearance of new vortex lines that split or reconnect.
VI. DISCUSSION AND CONCLUSIONS

In this paper two variants of open vortex lines in scalar BECs have been reported, having either one end or two ends of a vortex attached to a planar soliton. In the latter case, consisting of half vortex rings, we have shown that these configurations present long lifetimes for typical parameters of current experiments. For channeled condensates containing straight vortexes attached to solitons, we have demonstrated the existence of dynamically stable states and identified the bifurcation points of the first unstable modes. In both variants, a necessary condition for the corresponding configurations to be stationary requires that the vortex lines appear in pairs, as shown in Figs. 1, 2, 4, 5.

The stationary configurations we considered in this paper are either stable (vortex lines attached to planar dark solitons) or long-lived (U-shaped vortex lines), which indicate their feasibility for BEC experimental realizations. To this aim, the well-established experimental techniques in BECs developed for the observation of topical defects, such as optical phase imprinting [38, 39] or laser stirring [40], can be used. We propose here two possible ways for elongated condensates adequately devised to prevent the snaking instability [41]. By means of phase imprinting, both a transverse planar soliton and a pinned straight vortex along the z-axis could be simultaneously seeded. Alternatively, the laser stirring of the atomic cloud could be applied to drive the condensate into rotation around the z-axis, so that an energetically stable, singly charged vortex can be generated. After this, a planar soliton could be imaged onto the condensate by phase imprinting, in order to split the initial vortex into two vortex lines attached to the soliton. With regard to the realization of half vortex rings, the experimental procedures are more elaborate, since they would involve the controlled generation of vortex rings [42], within a regime of dynamical stability, followed by the phase imprinting of a soliton. These settings can open up a way to advance in the fairly unexplored domain of the interplay between vortices and solitons.

To summarize, we have demonstrated that stationary, robust states composed of vortex lines attached to planar dark solitons can be found in scalar BECs. Among them, we have reported on dynamically stable configurations in elongated systems for small values of the chemical potential. Our results follow from the Gross-Pitaevskii theory applied to realistic condensates of ultracold gases, and allow the study of vortex lines with Dirichlet boundary conditions. In addition, we have shown that in the hydrodynamic limit the dynamics of open vortex lines can be well characterized by the dual description of the Gross-Pitaevskii theory, which can be viewed as a (3+1)-dimensional effective string theory. This connection might pave the way to test some analytical predictions of string theory with experimental realizations in ultracold gases. To advance in this way, the further analysis of solutions to the equation of motion derived from the string functional Eq. (26) and the comparison with numerical simulations from the Gross-Pitaevskii equation are required, which will be reported elsewhere [43].

ACKNOWLEDGMENTS

We would like to thank S. Giaccari, J. Gomis, V. Pes-tun and S. Guber for many useful discussions. We are also very grateful to J. Brand, A. Bradley and B. P. Blakie for reading previous versions of this manuscript.
