Multi-product splitting and Runge-Kutta-Nyström integrators

Siu A. Chin
Department of Physics, Texas A&M University, College Station, TX 77843, USA

The splitting of $e^{h(A+B)}$ into a single product of $e^{hA}$ and $e^{hB}$ results in symplectic integrators when $A$ and $B$ are classical Lie operators. However, at high orders, a single product splitting, with exponentially growing number of operators, is very difficult to derive. This work shows that, if the splitting is generalized to a sum of products, then a simple choice of the basis product reduces the problem to that of extrapolation, with analytically known coefficients and only quadratically growing number of operators. When a multi-product splitting is applied to classical Hamiltonian systems, the resulting algorithm is no longer symplectic but is of the Runge-Kutta-Nyström (RKN) type. Multi-product splitting, in conjunction with a special force-reduction process, explains why at orders $p = 4$ and $6$, RKN integrators only need $p - 1$ force evaluations.

I. INTRODUCTION

The approximation of $e^{h(A+B)}$ to any order in $h$ via a single product decomposition

$$e^{h(A+B)} = \prod_i e^{a_i h A} e^{b_i h B}$$

is the basis of the splitting method\cite{1,2,3} for solving diverse classical\cite{14,5,6,7,8,9,10,11,12}, quantum mechanical\cite{13,14,15,16}, and stochastic evolution equations\cite{17,18}. The resulting algorithms are then symplectic, unitary and norm-preserving, respectively. However, at high orders, a single product splitting of the form (1) is very difficult to derive and the number of operators grows exponentially. This is easy to see: the error terms of the decomposition are governed by the fundamental Baker-Campbell-Hausdorff formula,

$$e^{hA} e^{hB} = e^{h(A+B)} + \frac{1}{2} h^2 [A,B] + \frac{1}{12} h^3 ([A,[A,B]]-[B,[A,B]]) + \cdots$$

where $[A,B] = AB - BA$ is the commutator bracket. Starting with the first error term $[A,B]$, successive higher order error terms are generated by further commutators of $A$ and $B$, such as $[A,[A,B]]$, $[B,[A,B]]$, $[A,[A,[A,B]]]$ and $[B,[A,[A,B]]]$, etc.. This rapid doubling is moderated somewhat by the Jacobi identity and the special form of operators $A$ and $B$, but the growth of these error terms is essentially exponential. This implies that high-order symplectic integrators must require many force-evaluations to eliminate these many error terms. For symplectic integrators, the minimum number of force-evaluations necessary at orders 4, 6, 8, 10 has been found empirically to be 3 (Ref.\cite{7,8,9,10}), 7 (Ref.\cite{10}), 15 (Ref.\cite{12}) and 31 (Ref.\cite{20}), respectively. The doubling trend is clearly visible and seems to be precisely twice plus one.

While symplectic integrators have many desirable conserving properties, such as the exact conservation of Poincaré invariants, they are not immune from the irreversible phase errors\cite{20,21,32,33} that directly affects the accuracy of trajectories. Since the accuracy of the trajectory is of paramount importance, regardless of how well some Poincaré invariants are preserved, it is less clear then, given the same number of force-evaluations, that a $2n$-order symplectic integrator should be preferred over a $2n+4$ or $2n+6$ order non-symplectic integrator, even for long term integrations.

This work shows that if one generalizes the decomposition of $e^{h(A+B)}$ to a sum of products, then for a special choice of the basis product, the problem reduces to that of simple extrapolation and can be solved easily to any even order. When applied to classical Hamiltonian systems, the resulting algorithms are no longer symplectic, but correspond to Runge-Kutta-Nyström (RKN) type integrators. Blanes, Casas and Ros\cite{14} and Blanes and Casas\cite{15} have previously shown that these extrapolated symplectic integrator enjoys better conservation properties than conventional RKN algorithms. Interestingly, multi-product splitting not only reproduces Nyström integrators at orders $p = 4$ and $6$ but also explain why they only need $p - 1$ force evaluations. At even higher order, these extrapolated RKN algorithms are surprisingly competitive with symplectic and other RKN integrators found in the literature.

II. MULTI-PRODUCT EXPANSION

If $e^{h(A+B)}$ were to be decomposed into a sum of products

$$e^{h(A+B)} = \sum_k c_k \prod_i e^{a_{k,i} h A} e^{b_{k,i} h B}$$

where $A, B$ are classical Lie operators. Interestingly, multi-product splitting not only reproduces Nyström integrators at orders $p = 4$ and $6$ but also explain why they only need $p - 1$ force evaluations. At even higher order, these extrapolated RKN algorithms are surprisingly competitive with symplectic and other RKN integrators found in the literature.
then there is tremendous freedom in the choice of \( \{c_k, a_{k,i}, b_{k,i}\} \). However, for the most general of applications, including solving time-irreversible diffusion type equations, one must keep the coefficients \( \{a_{k,i}, b_{k,i}\} \) positive. This crucial and deliberate choice distinguishes this work from previous extrapolations, which made no distinction between solving time-reversible and time-irreversible problems. If \( \{a_{k,i}, b_{k,i}\} \) were to be positive, then by Sheng’s theorem, any such individual product can at most be second order and some coefficients \( c_k \) must be negative. Thus without loss of generality, one can choose the simplest basis product as either one of the following symmetric second-order splittings

\[
T_2(h) = e^{\frac{1}{2}hB}e^{hA}e^{\frac{1}{2}hB}
\]

or

\[
T_2(h) = e^{\frac{1}{2}hA}e^{hB}e^{\frac{1}{2}hA}.
\]

The choice of a symmetric product is important, because it has only odd powers of \( h \),

\[
T_2(h) = \exp(h(A + B) + h^3E_3 + h^5E_5 + \cdots)
\]

where \( E_i \) are higher order error commutators of \( A \) and \( B \). It then follows that the \( k \)th power of \( T_2 \) at step size \( h/k \) is exactly given by

\[
T_2^k \left( \frac{h}{k} \right) = \exp(h(A + B) + k^{-2}h^3E_3 + k^{-4}h^5E_5 + \cdots).
\]

Thus the set of powers \( T_2^k(h/k) \) has well known error structure and forms a suitable basis for expanding \( e^{h(A+B)} \). For example, any two terms with \( k = l \) and \( k = m \) can approximate \( e^{h(A+B)} \) to fourth-order via

\[
e^{h(A+B)} = c_lT_2^l \left( \frac{h}{l} \right) + c_mT_2^m \left( \frac{h}{m} \right) + e_5(h^5E_5)
\]

with obvious solutions

\[
c_l = \frac{l^2}{l^2 - m^2}, \quad c_m = \frac{m^2}{m^2 - l^2}
\]

and error coefficient

\[
e_5 = -\frac{1}{l^2m^2}
\]

The RHS of (8) can also be written as

\[
T_2^l \left( \frac{h}{l} \right) + \frac{1}{(l/m)^2 - 1} \left[ T_2^l \left( \frac{h}{l} \right) - T_2^m \left( \frac{h}{m} \right) \right]
\]

which coincide with the diagonal elements of the Richardson-Aitken-Neville extrapolation table. Here, we do not do the extrapolation numerically, instead, we give an analytical formula for extrapolating to any even order. More generally, for a given set of \( n \) distinct whole numbers \( \{k_1, k_2, \ldots, k_n\} \), one can form a \( 2n \)-order approximation of \( e^{h(A+B)} \) via

\[
e^{h(A+B)} = \sum_{i=1}^{n} c_iT_2^{k_i} \left( \frac{h}{k_i} \right) + e_{2n+1}(h^{2n+1}E_{2n+1}).
\]

The expansion coefficients \( c_i \) are determined by a specially simple Vandermonde equation,

\[
\begin{pmatrix}
1/k_1^{-2} & 1/k_2^{-2} & 1/k_3^{-2} & \cdots & 1/k_n^{-2} \\
1 & k_2^{-4} & k_3^{-4} & \cdots & k_n^{-4} \\
k_1^{-2(n-1)} & k_2^{-2(n-1)} & k_3^{-2(n-1)} & \cdots & k_n^{-2(n-1)}
\end{pmatrix}
\begin{pmatrix}
c_1 \\
c_2 \\
c_3 \\
\vdots \\
c_n
\end{pmatrix}
= \begin{pmatrix}
1 \\
0 \\
0 \\
\vdots \\
0
\end{pmatrix}
\]
with closed form solutions
\[ c_i = \prod_{j=1(i\neq j)}^{n} k_i^2 / k_j^2 \]  
and error coefficient,
\[ e_{2n+1} = (-1)^{n-1} \prod_{i=1}^{n} 1 / e_i^2 . \]

The closed forms (14) and (15) are the key results of this multi-product expansion. All error terms of the same order, rather then be forced to zero individually, are extrapolated to zero simultaneously. The Vandermonde equation (13) is a special case of extrapolated symplectic algorithms considered by Blanes, Casas and Ros. However, they did not obtain the exact solution given by (14). The proof that (14) is the exact solution is given in Appendix A. According to Blanes, Casas and Ros, this class of extrapolated integrator is symplectic to order 2n+3, which at higher orders, can easily exceed one’s machine precision. That is, at sufficiently high orders, these extrapolated symplectic algorithms are, up to machine precision, indistinguishable from truly symplectic algorithms.

Since a 2n-order expansion is completely characterized by a set of n whole numbers \( \{k_1, k_2, ..., k_n\} \), the resulting algorithm will be referred to as the \( \{k_1, k_2, ..., k_n\} \)-integrator. The error coefficient (15) implies that, if the number of application of \( T_2 \) is fixed,
\[ \sum_{i=1}^{n} k_i = K \]  
then the optimal algorithm with the least error is given by a set of n distinct whole numbers \( \{k_i\} \) closest to INT(\( K/n \)) satisfying (16). On the other hand, at order 2n, the minimum number of \( T_2 \) required is given by the natural sequence \( \{k_i\} = \{1, 2, 3, ..., n\} \), corresponding to approximating \( e^{h(A+B)} \) via
\[ e^{h(A+B)} = \sum_{k=1}^{n} c_k T_2^k \left( \frac{h}{k} \right) + e_{2n+1}(h^{2n+1}E_{2n+1}) \]  
with \( n(n+1)/2 \) applications of \( T_2 \) and an error coefficient of
\[ e_{2n+1} = (-1)^{n-1} 1 / (n!)^2 . \]

The simplicity of these results make multi-product splitting algorithms extremely easy to analyze and implement.

From (14), the minimum-\( T_2 \) expansions of orders four to ten are given by
\[ T_4(h) = -\frac{1}{3} T_2(h) + \frac{4}{3} T_2^2 \left( \frac{h}{2} \right) \]  
\[ T_6(h) = \frac{1}{24} T_2(h) - \frac{16}{15} T_2^2 \left( \frac{h}{2} \right) + \frac{81}{40} T_2^3 \left( \frac{h}{3} \right) \]  
\[ T_8(h) = -\frac{1}{360} T_2(h) + \frac{16}{45} T_2^2 \left( \frac{h}{2} \right) - \frac{729}{280} T_2^3 \left( \frac{h}{3} \right) + \frac{1024}{315} T_2^4 \left( \frac{h}{4} \right) \]  
\[ T_{10}(h) = \frac{1}{8640} T_2(h) - \frac{64}{945} T_2^2 \left( \frac{h}{2} \right) + \frac{6561}{4480} T_2^3 \left( \frac{h}{3} \right) - \frac{16384}{2835} T_2^4 \left( \frac{h}{4} \right) + \frac{390625}{72576} T_2^5 \left( \frac{h}{5} \right) . \]

In contrast to a single product decomposition, whose coefficients \( \{a_i, b_i\} \) are generally irrational and must be determined order-by-order numerically with limited precision, the multi-product expansion has only rational coefficients and are given analytically by (14) for all even orders.

The operator extrapolation here is at once more general and simpler than extrapolating solutions of differential equations. The general expansion (17) can be applied to any evolution operator \( e^{h(A+B)} \) in terms of \( T_2 \), with known second order error structure (6). There is no need to devise and prove, a second-order solution in advance. The low order operator extrapolation (19) has been used previously in different contexts. Here, we provide a systematic expansion to any even order and point out the connection between symplectic and RKN integrators.
III. DERIVING RKN INTEGRATORS

As emphasized in the last section, the multi-product expansion (17) is an extrapolated operator approximation to the evolution operator \( e^{h(A+B)} \) and can be applied to many different types of equations. Its applications to quantum and stochastic evolution equations have already proven to be highly successful. Here, we will concentrate on its use in solving classical dynamic problems.

If \( e^{h(A+B)} \) is decomposed into a sum of products as in (17), then the resulting algorithm will no longer be symplectic. This is because for more than one product, cross terms will spoil the usual proof of symplecticity (See Ref. [4], Theorem 1.). As we will show, multi-product splitting now produces RKN type integrators.

For solving Hamilton’s equation in the form,

\[
\frac{dq}{dt} = v \quad \frac{dv}{dt} = a(q)
\]

the operators are

\[
A = \sum_i v_i \frac{d}{dq_i} \quad B = \sum_i a_i(q) \frac{d}{dv_i}
\]

and where we have abbreviated \( v = p/m \) and \( a(q) = F(q)/m \). Thus (4) corresponds to the velocity-form of the Verlet algorithm (VV):

\[
\begin{align*}
v_1 & = v_0 + \frac{h}{2} a(q_0) \\
q_1 & = q_0 + h v_1 \\
v_2 & = v_1 + \frac{h}{2} a(q_1)
\end{align*}
\]

and (5) corresponds to the position-form of the Verlet algorithm (PV):

\[
\begin{align*}
q_1 & = q_0 + \frac{h}{2} v_0 \\
v_1 & = v_0 + h a(q_1) \\
q_2 & = q_1 + \frac{h}{2} v_1.
\end{align*}
\]

The last numbered variables are the updated variables. Both VV and PV are second order symplectic integrators. The operator \( T^k_2(h/k) \) simply iterating either algorithm \( k \) times at step size \( h/k \) and is therefore also symplectic. The PV algorithm uses only one force evaluation per update. If \( T_2 \) is taken to be PV, then the extrapolated integrators of order \( 2n \), as exemplified by (19)-(22), only require \( n(n+1)/2 \) force-evaluations. The minimal integrator of orders 4, 6, 8 and 10 requires only 3, 6, 10, and 15 force evaluations, respectively.

If \( T_2 \) is taken to the VV algorithm, since all products use the same starting force, each \( T^k_2(h/k) \) for \( k > 2 \) also uses only \( k \) force-evaluations. However, \( T_2(h) \) must then evaluate the initial force for the rest of the product and its own final force. Thus \( T_2(h) \) requires two force-evaluations, giving the final force count as \( n(n+1)/2 + 1 \).

There are other possible extrapolation methods, such as

\[
T_6(h) = -\frac{1}{15} T_4(h) + \frac{16}{15} T_2^2 \left( \frac{h}{2} \right)
\]

which is similar to the triplet concatenation for symplectic integrators\(^7\). However, such an iterative extrapolation, which triples the number of force-evaluations in going from order \( 2n \) to \( 2n + 2 \), is not competitive with (17)’s linear increase of only \( n + 1 \) additional force-evaluations.

To see how the expansion (17) results in RKN integrators, let’s takes \( T_2 \) to be VV, then the extrapolation (19) produces the following fourth-order, \( \{1, 2\} \)-integrator

\[
\begin{align*}
q & = q_0 + h v_0 + \frac{h^2}{6} (a_0 + 2a_{1/2}) \\
v & = v_0 + \frac{h}{6} (a_0 + 4a_{1/2} + 2a_{2/2} - a_{1/1})
\end{align*}
\]
where we have systematically denoted the force evaluation point of $T_2^k(h/k)$ at the intermediate step $(i/k)h$ as $q_{i/k}$ and the resulting force as $a_{i/k} = a(q_{i/k})$, with $a_0 = a(q_0)$. The final force evaluation point of $T_2^k(h)$, the midpoint of $T_2^k(h/2)$, and the final position of $T_2^k(h/2)$ are given by

$$
q_{1/1} = q_0 + h v_0 + \frac{h^2}{2} a_0 \\
q_{1/2} = q_0 + \frac{h}{2} v_0 + \frac{h^2}{8} a_0 \\
q_{2/2} = q_0 + h v_0 + \frac{h^2}{4} (a_0 + a_{1/2}) .
$$

The resulting integrator \cite{28} appears to require four force-evaluations, in accordance with the formula $n(n+1)/2 + 1$. However, a key observation here is that force subtractions at the *same time step* can be combined into a single force evaluation. Let

$$
\delta q_2 = q_{2/2} - q_{1/1} = \frac{h^2}{4} (a_{1/2} - a_0) \approx O(h^3)
$$

then the subtraction of two forces gives,

$$
2a_{2/2} - a_{1/1} = 2a(q_{1/1} + \delta q_2) - a(q_{1/1})
= a(q_{1/1} + 2\delta q_2) + O(h^6)
= a \left( q_0 + h v_0 + \frac{1}{2} h^2 a_{1/2} \right) + O(h^6).
$$

The total number of force evaluations is reduced from four to three and \cite{28} reproduces Nyström’s original fourth-order integrator\cite{28,29}. Thus we have shown analytically that, the subtraction of two *symplectic* integrators reproduces Nyström’s original integrator. This connection between extrapolated symplectic integrators and Nyström’s integrators has not been appreciated previously.

If $T_2(h)$ is taken to be PV, the corresponding $\{1, 2\}$-integrator with three force-evaluations is given by

$$
x = x_0 + h v_0 + \frac{h^2}{6} (3a_{1/4} - a_{1/2} + a_{3/4})
\v = v_0 + \frac{h}{3} (2a_{1/4} - a_{1/2} + 2a_{3/4}).
$$

Since PV and VV based algorithms have different force-evaluation points, to avoid confusion, we will denote the positions of PV-based integrator as $x_{i/k}$. Here, the force-evaluation points are

$$
x_{1/4} = x_0 + \frac{h}{4} v_0 \\
x_{1/2} = x_0 + \frac{h}{2} v_0 \\
x_{3/4} = x_0 + \frac{3}{4} h v_0 + \frac{h^2}{4} a_{1/4} .
$$

All such PV-based integrators are non-FSAL (First Step As Last) RKN integrators in that the force is never evaluated initially. The explicit force subtraction will be more susceptible to round-off errors. However, this fourth-order integrator is superior to the Nyström integrator when solving Kepler’s orbit and concerns for round-off errors are moderated by the wide use of quadruple and multi-precision packages.

To compare the long time integration error of numerical algorithms, it is useful to solve Kepler’s orbit in two dimension,

$$
a_x = \frac{q_x}{q^3} \quad a_y = -\frac{q_y}{q^3} \quad q = \sqrt{q_x^2 + q_y^2}
$$

with initial conditions

$$
v_x = 0 \quad v_y = \sqrt{\frac{1 - e}{1 + e}} \quad q_x = 1 + e \quad q_y = 0
$$
where \( e \) is the eccentricity of the orbit. The resulting energy and period are respectively \(-1/2\) and \(2\pi\). This set of initial conditions is chosen (instead of the usual one in the literature) because it is non-singular as \( e \to 1 \) and the orbit’s semi-major axis is always along the x-axis for all values of \( e \). Both are useful for computing the precession error of Kepler’s orbit at high eccentricity.

To gauge the accuracy of the trajectory intrinsically, without any external comparison, we monitor the irreversible phase error\(^{30,31}\) by computing the rotation angle per period, \( \Delta \theta \), of the Laplace-Runge-Lenz (LRL) vector\(^{32,33}\):

\[
A = v \times L - \frac{q}{q} \tag{37}
\]

with \( L = q \times v \). If the orbit is exact, then the LRL vector would remain constant pointing along the semi-major axis of the orbit. If \( \Delta \theta \neq 0 \), then the orbit will have precessed an angle of \( \Delta \theta \) after each period. (This is the advance of the perihelion of solar planets.) Thus \( \Delta \theta \) is a much more direct measure of the trajectory’s accuracy than the energy error. This precession error grows linearly with time as \( m \Delta \theta \), where \( m \) is the number of periods, even for symplectic integrators\(^{30,31}\). The corresponding precession error coefficient is extracted by dividing \( \Delta \theta \) by \( h^4 \) using smaller and smaller \( h \) until

\[
\lim_{h \to 0} \frac{\Delta \theta}{h^4} = e_P
\tag{38}
\]

is independent of \( h \). The coefficient \( e_P \) as a function of the eccentricity is therefore a unique error signature of each fourth-order integrator independent of the step size.

In Fig.1 we compare the precession error coefficients of four distinct fourth-order integrators with only three force evaluations. The symplectic Forest-Ruth (FR) integrator\(^2\), the forward integrator \( A^{25,27} \), the Nyström integrator (N) given by \( \{28\}, \{32\} \) and the minimal fourth-order \{1, 2\}-integrator M4, given by \( \{33\} \). The forward integrator \( A' \) has only positive splitting coefficients \( a_i \) and \( b_i \). The convergence of \( \{33\} \) is seen near \( h = 2\pi/3000 \); the final value used is \( h = 2\pi/5000 \). The coefficient \( e_P \) grows steeply with \( e \), by four orders of magnitude from \( e = 0.4 \) to \( e = 0.9 \), but all integrators showed similar dependence on \( e \). It is well known that the precession error of the symplectic FR integrator is greater than that of RKN algorithms\(^{30,31}\) such as N, but it was not known previously that M4 is so much better than FR and N. The error coefficient \( e_P \) at \( e = 0.9 \) for FR, N, \( A' \) and M4 are -23.1\( \times 10^4 \), 7.1\( \times 10^4 \), -1.4\( \times 10^4 \) and -1.1\( \times 10^4 \), respectively.

IV. SIXTH ORDER RKN INTEGRATORS

If \( T_2(h) \) is taken to be VV, the difference between the two force evaluation points at the same intermediate time step, such as \( \{20\} \), is always of order \( O(h^3) \) and the resulting force subtraction, such as \( \{32\} \), is of order \( O(h^6) \). This immediately suggests that the three final force evaluations in the \{1, 2, 3\}-integrator can be collapsed into one, yielding a sixth order algorithm with only five force-evaluations. This is indeed the case. The \{1, 2, 3\}-integrator, according to \( \{20\} \), is given by

\[
q = q_0 + hv_0 + \frac{h^2}{120}(11a_0 + 54a_{1/3} - 32a_{1/2} + 27a_{2/3}), \tag{39}
\]

\[
v = v_0 + \frac{h}{240}(22a_0 + 162a_{1/3} - 128a_{1/2} + 162a_{2/3})
+ 8a_{3/3} - 64a_{2/2} + 5a_{1/1}), \tag{40}
\]

with three additional force evaluations at:

\[
q_{1/3} = q_0 + \frac{h}{3}v_0 + \frac{h^2}{18}a_0, \tag{41}
\]

\[
q_{2/3} = q_0 + \frac{2}{3}hv_0 + \frac{h^2}{9}(a_0 + a_{1/3}), \tag{42}
\]

\[
q_{3/3} = q_0 + hv_0 + \frac{h^2}{18}(3a_0 + 4a_{1/3} + 2a_{2/3}). \tag{43}
\]

Let

\[
\delta q_3 = q_{3/3} - q_{1/1} = \frac{1}{9}h^2(2a_{1/3} + a_{2/3} - 3a_0) \approx O(h^3), \tag{44}
\]
then the three final-step force-evaluations can be collapsed into one,

\[ 81a_{3/3} - 64a_{2/2} + 5a_{1/1} = 22a(q_1) + O(h^6), \]  

(45)

with

\[ \bar{q}_1 = q_{1/1} + \frac{1}{22}(81\delta q_3 - 64\delta q_2) \]
\[ = q_0 + h v_0 + \frac{h^2}{22} (18a_{1/3} - 16a_{1/2} + 9a_{2/3}). \]  

(46)

The force consolidation (45) now renders (40) symmetric,

\[ v = v_0 + \frac{h}{240} (22a_0 + 162a_{1/3} - 128a_{1/2} + 162a_{2/3} + 22a_1). \]  

(47)

This sixth order integrator seems not to be known prior to this work. The well known sixth order integrator with five force evaluations due to Albrecht, can be derived from an alternative expansion,

\[ T_6(h) = \frac{1}{45} T_2(h) - \frac{4}{9} T_2^2 \left( \frac{h}{2} \right) + \frac{64}{45} T_2^4 \left( \frac{h}{4} \right), \]

(48)
corresponding to the integrator \( \{1, 2, 4\}, \)

\[ q = q_0 + h v_0 + \frac{h^2}{90} (7a_0 + 24a_{1/4} + 16a_{2/4} - 10a_{1/2} + 8a_{3/4}), \]  

(49)

\[ v = v_0 + \frac{h}{90} (7a_0 + 32a_{1/4} + 32a_{2/4} - 20a_{1/2} + 32a_{3/4} \]
\[ + 16a_{4/4} - 10a_{2/2} + a_{1/1}). \]  

(50)

with four additional force evaluations at

\[ q_{1/4} = q_0 + \frac{h}{4} v_0 + \frac{h^2}{32} a_0, \]  

(51)

\[ q_{2/4} = q_0 + \frac{h}{2} v_0 + \frac{h^2}{16} (a_0 + a_{1/4}), \]  

(52)

\[ q_{3/4} = q_0 + \frac{3}{4} h v_0 + \frac{h^2}{32} (3a_0 + 4a_{1/4} + 2a_{2/4}), \]  

(53)

\[ q_{4/4} = q_0 + h v_0 + \frac{h^2}{16} (2a_0 + 3a_{1/4} + 2a_{2/4} + a_{3/4}). \]  

(54)

This algorithm nominally requires eight force evaluations, but forces can now be collapsed at \( h/2 \) and at \( h \). At \( h/2 \), one has

\[ 16a_{2/4} - 10a_{1/2} = 6a(q_{1/2}^\star) + O(h^6), \]  

(55)

where the new half time-step evaluation point is

\[ q_{1/2}^\star = q_0 + \frac{h}{2} v_0 + \frac{h^2}{24} (4a_{1/4} - a_0). \]  

(56)

Similarly, the three force evaluations at \( h \) can be collapsed into one,

\[ 16a_{1/4} - 10a_{2/2} + a_{1/1} = 7a(q_{1}^\dagger) + O(h^6), \]  

(57)

where

\[ q_{1}^\dagger = q_0 + h v_0 + \frac{h^2}{14} (6a_{1/4} + 4a_{2/4} - 5a_{1/2} + 2a_{3/4}). \]  

(58)
The number of force-evaluations can be reduced from eight to five if both \( q_{2/4} \) and \( q_{1/2} \) can be replaced everywhere by \( q_{1/2}^* \). However, replacing \( a_{2/4} \) in \( q_{3/4} \) by \( a_{1/2}^* \) would yield

\[
q_{3/4}^* = q_0 + \frac{3}{4} h v_0 + \frac{h^2}{32} \left( 3a_0 + 4a_{1/4} + 2a_{1/2}^* \right)
\]

\[
= q_{3/4} + \frac{h^2}{16} \left( a_{1/2}^* - a_{2/4} \right)
\]

\[
= q_{3/4} + O(h^5),
\]

and the resulting \( 32a_{3/4}^* \) term in (50) would produce an error of \( O(h^6) \), spoiling the algorithm. Remarkably, replacing \( q_{2/4} \) and \( q_{1/2} \) everywhere by \( q_{1/2}^* \) in (55) defines

\[
q_{1}^* = q_0 + h v_0 + \frac{h^2}{14} \left( 6a_{1/4} - a_{1/2}^* + 2a_{3/4}^* \right)
\]

\[
= q_{1} + \frac{h^2}{14} \left( a_{1/2}^* + 4a_{2/4} - 5a_{1/2} \right),
\]

\[
= q_{1} + O(h^5),
\]

and the resulting \( O(h^6) \) error of \( 7a_{1}^* \) in (55) exactly cancels that of \( 32a_{3/4}^* \). Thus, one recovers Albrecht’s integrator:

\[
q = q_0 + h v_0 + \frac{h^2}{90} \left( 7a_0 + 24a_{1/4} + 6a_{1/2}^* + 8a_{3/4}^* \right) + O(h^7)
\]

\[
v = v_0 + \frac{h}{90} \left( 7a_0 + 32a_{1/4} + 12a_{1/2}^* + 32a_{3/4}^* + 7a_{1}^* \right) + O(h^7).
\]

Within the context of multi-product expansion, these are the only two sixth-order integrators possible with only five force evaluations. Again, we have shown analytically that the extrapolation of these second-order symplectic integrators produces sixth-order RKN integrators.

To compare integrators of the same order but with different number of force evaluations, we compute the precession error \( \Delta \theta \) at \( e = 0.9 \) as a function of \( N \), the number of force-evaluations used. The results for fourth-order algorithms are shown in Fig.2. Y6 is Yoshida’s symplectic algorithm with the minimum 7 force evaluations. KL6 is a much improved version by Kahan and Li with 9 force evaluations. A6 and M6 are Albrecht’s and the PV-based, minimal \{1,2,3\}-integrator with 5 and 6 force-evaluations respectively. While KL6’s error is only half of Y6’s at \( 10^5 \) force-evaluations, their respective error are nearly 50 and 100 times larger than those of RKN integrators A6 and M6. This calculation was carried out in quadruple-precision using the widely available free software by Miller.

V. HIGHER ORDER COMPARISONS

Since the force reduction process considered is only of \( O(h^6) \), this process will no longer be effective for integrators beyond sixth-order. Thus beyond sixth-order, some other force reduction processes must be found if the number of force-evaluation is to be less than \( n(n+1)/2 \). At higher orders, since the expansion coefficients (14) are known explicitly, it is trivial to write a subroutine for (26) and simply call it according the multi-product expansion (17). Alternatively, one can also construct them from the Aitken-Neville table, as done conventionally. It is of interest to compare these extrapolated RKN integrators at high orders with existing symplectic and specially derived RKN integrators found in the literature.

In Fig.3 we compare some well known higher order integrators with the PV-based, minimal extrapolated integrators (17). KL8 and SS10 are eighth and tenth order symplectic integrators by Kahan and Li and Sofroniou and Spalletta with 17 and 35 force evaluations respectively. Both are recommended by Ref.2. Because of their large number of force-evaluations, they are not competitive in a precision-effort comparison as shown in Fig.3. At \( N = 10^5 \), the error of KL8 is more than 300 times that of the PV-based \{1,2,3,4\}-integrator denoted simply as 8 rather than M8. Similarly, the error of SS10 at \( N = 10^5 \) is about 100 times that of the minimal \{1,2,3,4,5\}-integrator denoted as 10. DP10 and DP12 are the RKN integrator-pair by Dormand, El-Mikkawy and Prince with 17 force evaluations. The coefficients for this integrators-pair were taken from Brankin et al. and converted to quadruple precision. DP10 is comparable to 10, which uses 15 force evaluations. DP12’s error at \( N = 10^5 \) is 10 times smaller than 12. However, DP12’s superior performance can be quickly matched by going to integrator 14, whose error is then 100 times smaller than DP12 at \( N = 10^5 \).
Fig. 3 implies that the most efficient integrator for attaining a given level of precision is never a fixed order integrator. As one demands greater and greater precision, one must increase the order of the integrator accordingly. In Fig. 3, the error curve of the $2n + 2$ integrator is plotted only when it is below that of the $2n$ integrator. The enveloping error curve is steeper than any fixed order integrator. This maximum efficiency can be achieved only when one has the mean of producing an arbitrary high-order integrator at will, as it is done here. The highest order considered in Fig. 3 is 16 because quadruple precision is inadequate for precision below $10^{-30}$.

VI. SUMMARY AND CONCLUSIONS

In this work, we have generalized the single product decomposition of the evolution operator $e^{i(A+B)t}$ to that of a sum of products. By using powers of $T_2$ as basis products, the multi-product expansion reduces to that of a simple extrapolation, with analytically known solutions. Because the extrapolation is formulated on the level of operators, it can be applied with great generality in solving diverse evolution equations not only in classical mechanics but also in quantum and stochastic dynamics.

A multi-product expansion loses some desirable properties, such as not being symplectic, unitary, norm preserving, etc., as compared to a single product decomposition. However, at high orders, it gains in economy, needing only a quadratic, rather than an exponential number of operators. This is a vital consideration when high precision and high order results are needed.

In applying to classical Hamiltonian dynamics, this work showed that extrapolating symplectic integrators produces RKN integrators. The process of force consolidation provided a simple explanation for why $p - 1$ force evaluations are sufficient for RKN integrators at orders $p = 4$ and 6. An order-barrier then naturally arises when forces can longer be consolidated at higher $p$. Moreover, this work showed that, there exists a sequence of easily implemented, $2n$-order extrapolated RKN integrators, with only $n(n + 1)/2$ force evaluations. Thus any other RKN integrator with fewer force evaluations is special and must embody some unique force consolidation schemes. These extrapolated RKN integrators are surprisingly competitive with existing symplectic and specially devised RKN algorithms in solving the Kepler problem. Since this series of extrapolated RKN integrators can be easily produced by anyone, they can serve as a common benchmark by which more sophisticated high order integrators can be judged. For example, of all the integrators compared in this work, only DP12 has outperformed its corresponding extrapolated RKN integrator by having fewer force evaluations (17) than of $n(n + 1)/2$ ($=21$). Thus DP12 must possess some highly nontrivial force consolidation schemes.

APPENDIX A: PROVING THE SOLUTION

To solve the Vandermonde equation (13) for $\{c_i\}$, let $x_i = k_i^{-2}$ so that (13) reads conventionally

$$
\begin{pmatrix}
 1 & 1 & 1 & \ldots & 1 \\
 x_1 & x_2 & x_3 & \ldots & x_n \\
 x_1^2 & x_2^2 & x_3^2 & \ldots & x_n^2 \\
 \vdots & \vdots & \vdots & \ddots & \vdots \\
 x_1^{n-1} & x_2^{n-1} & x_3^{n-1} & \ldots & x_n^{n-1}
\end{pmatrix}
\begin{pmatrix}
 c_1 \\
 c_2 \\
 c_3 \\
 \vdots \\
 c_n
\end{pmatrix}
= \begin{pmatrix}
 1 \\
 0 \\
 0 \\
 \vdots \\
 0
\end{pmatrix}
\quad (A1)
$$

Consider the usual Lagrange interpolation at $n$ points $\{x_1, x_2, \ldots, x_n\}$ with values $\{y_1, y_2, \ldots, y_n\}$. The interpolating $n-1$ degree polynomial is given by

$$
f(x) = \sum_{i=1}^{n} y_i L_i(x),
\quad (A2)
$$

where $L_i(x)$ are the Lagrange polynomials given by

$$
L_i(x) = \prod_{j=1,\neq i}^{n} \frac{(x - x_j)}{(x_i - x_j)}.
\quad (A3)
$$

Since by construction

$$
L_i(x_k) = \delta_{ik}
\quad (A4)
$$
the interpolation polynomial (A2) correctly gives,
\[ f(x_k) = \sum_{i=1}^{n} y_i L_i(x_k) = \sum_{i=1}^{n} y_i \delta_{ik} = y_k. \]  
\(\text{(A5)}\)

Now let \(y_i = x_i^m\) for \(0 \leq m \leq n - 1\), then the interpolating polynomial
\[ f(x) = \sum_{i=1}^{n} x_i^m L_i(x) \]  
\(\text{(A6)}\)

and the function
\[ g(x) = x^m \]  
\(\text{(A7)}\)

both interpolate the same set of points. Since interpolating polynomials of the same order are unique, we must have \(f(x) = g(x)\) and hence
\[ \sum_{i=1}^{n} x_i^m L_i(x) = x^m. \]  
\(\text{(A8)}\)

Writing this out in matrix form yields
\[
\begin{pmatrix}
1 & 1 & 1 & \ldots & 1 \\
x_1 & x_2 & x_3 & \ldots & x_n \\
x_1^2 & x_2^2 & x_3^2 & \ldots & x_n^2 \\
\vdots & \vdots & \vdots & \ldots & \vdots \\
x_1^{(n-1)} & x_2^{(n-1)} & x_3^{(n-1)} & \ldots & x_n^{(n-1)}
\end{pmatrix}
\begin{pmatrix}
L_1(x) \\
L_2(x) \\
L_3(x) \\
\vdots \\
L_n(x)
\end{pmatrix}
= 
\begin{pmatrix}
1 \\
x \\
x^2 \\
\vdots \\
x^{n-1}
\end{pmatrix} 
\]  
\(\text{(A9)}\)

Compare this to (A1), we immediately see that the solution is
\[ c_i = L_i(0) = \prod_{j=1(\neq i)}^{n} \frac{x_j}{x_j - x_i} = \prod_{j=1(\neq i)}^{n} \frac{k_i^j}{k_i^j - k_j^i} \]  
\(\text{(A10)}\)

This proof is a simple application of the more general result of inverting the Vandermonde matrix.\(\text{[44]}\)
