Abstract

We describe a meta-querying system for databases containing queries in addition to ordinary data. In the context of such databases, a meta-query is a query about queries. Representing stored queries in XML, and using the standard XML manipulation language XSLT as a sublanguage, we show that just a few features need to be added to SQL to turn it into a fully-fledged meta-query language. The good news is that these features can be directly supported by extensible database technology.

1 Introduction

Enterprise databases often contain not only ordinary data, but also queries. Examples are view definitions in the system catalog; usage logs or workloads; and stored procedures as in SQL/PSM or Postgres \textsuperscript{22}. Unfortunately, these queries are typically stored as long strings, which makes it hard to use standard SQL to express meta-queries: queries about queries. Meta-querying is an important activity in situations such as advanced database administration, database usage monitoring, and workload analysis. Examples of meta-queries to a usage log are:

1. Which queries in the log do the most joins?

2. Which queries in the log return an empty answer on the current instance of the database?

3. View expansion: replace, in each query in the log, each view name by its definition as given in the system catalog.

4. Given a list of new view definitions (under the old names), which queries in the log give a different answer on the current instance under the new view definitions?

Query 1 is \textit{syntactical}: it only queries the stored queries on the basis of their expressions. Query 2 is \textit{semantical}: its answer depends on the results of dynamically executing the stored queries. Query 3 is again syntactical, but more so than query 1 in that it also performs syntactical transformations. Query 4 is syntactical and semantical together.

To express meta-queries, database administrators and other advanced users typically resort to a programming language like Perl, in combination with Dynamic SQL. It would be much nicer if they would not have to “leave” the database system and could express their meta-queries directly in Interactive SQL. Indeed, already in 1993, in his SIGMOD Innovations Award speech, Jim Gray urged the database community to lower the wall between data and programs. In the same vein, the Asilomar Report puts the unification between programs and data high on the database research agenda \textsuperscript{2}. As queries are an important
kind of program in the context of databases, support for meta-querying thus seems to be a step in the right direction towards understanding how we can unify programs and data in database systems.

In this paper, we present a practical meta-querying system based on the relational model. Our main design goal was to use current DBMS technology and only extend standard SQL with specific meta-querying features where necessary. Stored queries are represented as syntax trees in XML format. This representation provides a convenient basis for syntactical meta-querying. Indeed, rather than reinventing the wheel and designing a new sublanguage for syntactical manipulation of stored queries, it allows us to use the standard XML transformation language XSLT for this purpose. Many syntactical meta-queries can then directly be expressed simply by allowing XSLT function calls within SQL expressions.\footnote{We embrace XSLT because it is the most popular and stable standard general-purpose XML manipulation language to date. When other languages, notably XQuery \cite{XQuery}, will take over this role, it will be an easy matter to substitute XSLT by XQuery in our overall approach.}

This combination of SQL and XSLT gives us a basic level of expressive power, but for more complex syntactical meta-queries we need a bit more. To this end, we enrich the SQL language with XML variables which come in addition to SQL's standard range variables. XML variables range not over the rows of a table, but rather over the subelements of an XML tree. The range can be narrowed by an XPath expression. (XPath is the sublanguage of XSLT used to locate subelements of XML documents.) XML variables thus allow us to go from an XML document to a set of XML documents. Conversely, we also add XML aggregation \cite{XMLAgg}, which allows us to go from a set of XML documents to a single one.

SQL combined with XSLT and enriched with XML variables and aggregation offers all the expressive power one needs for ad-hoc syntactical meta-querying. To allow for semantical meta-querying as well, it now suffices to add an evaluation function, taking the syntax tree of some query as input, and producing the table resulting from executing the query as output. We note that a similar evaluation feature was already present in the Postgres system.

What we obtain is Meta-SQL: a practical meta-query language. Meta-SQL has as advantage that it is not “yet another query language”: it is entirely compatible with modern SQL implementations offered by contemporary extensible database systems. Indeed, these systems already support calls to external functions from within SQL expressions, which allows us to implement the XSLT calls. Furthermore, XML variables and the evaluation function can be implemented using set-valued external functions. As we will show, the powerful feature of “lateral derived tables”, part of the SQL:1999 standard, turns out to be crucial to make this work. XML aggregation, finally, can be implemented as a user-defined aggregate function.

We emphasize again that we are not proposing yet another database language. Instead, our main design goal was to stick as closely as possible to standard SQL. Of course, a drastic alternative is to abandon the relational model altogether and move to, e.g., an XML-XQuery environment, where meta-querying does not pose any problem. However, given the widespread use of relational databases, a conservative approach such as ours remains important.

This paper is further organized as follows. In Section 2, we combine SQL with XSLT. In Section 3, we add XML variables. In Section 4, we move on to semantical meta-
querying. In Section 5, we describe how Meta-SQL can be implemented using extensible database technology. We give some experimental performance results of our prototype in Section 6. In Section 7, we conclude with a discussion of our approach.

2 SQL + XSLT

Consider a standard relational database, except that in a table some columns can be marked to be of type “XML”. In any row of that table, the component corresponding to a column of type XML holds an XML document. At the present conceptual level, we do not yet care about how this is implemented.

XSLT [28] is a widely used manipulation language for XML documents. An XSLT program takes an XML document as input, and produces as output another XML document (which could be in degenerate form, holding just a scalar value like a number or a string). Using the XSLT top-level parameter binding mechanism [28], programs can also take additional parameters as input.\(^2\)

Hence, to query databases containing XML, it seems natural to extend SQL by allowing calls to XSLT functions, in the same way as extensible database systems extend SQL with calls to external functions. However, in these systems, external functions have to be pre-compiled and registered before they can be used. In Meta-SQL, the programmer merely includes the source of the needed XSLT functions and can then call them directly.

Let us see an example of all this, at the same time applying it to meta-querying. Consider a simplified system catalog table, called Views, containing view definitions. There is a column name of type string, holding the view name, and a column def of type XML, holding the syntax tree of the SQL query defining the view, in XML format. For example, over a movies database, suppose we have a view DirRatings defined as follows:

```
select director, avg(rating) as avgrat
from Movies group by director
```

Then table Views would have a row with value for name equal to 'DirRatings', and value for def equal to the following XML document:

```
<query>
  <select>
    <sel-item>
      <column>director</column>
    </sel-item>
    <sel-item>
      <aggregate><avg/>
        <column-ref>
          <column>rating</column>
        </column-ref>
      </aggregate>
      <alias>avgrat</alias>
    </sel-item>
  </select>
  <from>
    <table-ref>
      <table>Movies</table>
    </table-ref>
  </from>
  <group-by>
    <column-ref>
      <column>director</column>
    </column-ref>
  </group-by>
</query>
```

Figure 1 shows the same document as a DOM tree [3], which is perhaps clearer.

To achieve uniformity in the specific XML format for representing SQL syntax trees, we must agree on some fixed BNF syntax for SQL. A BNF grammar can be easily transformed into an XML DTD [25], which then

\(^2\)In this paper, we cannot include a tutorial on XSLT, for which we refer to the Web or to the literature [23, 13].
specifies the XML format to use. In this paper, we use the BNF grammar given by Date [6]. The derived DTD is given in Appendix A.

Now recall the first example meta-query from the Introduction, but applied to our Views table: “which queries do the most joins?” For simplicity of exposition, let us identify the number of joins an SQL query does with the number of table names occurring in it. To express this meta-query in Meta-SQL, we write an auxiliary XSLT function count_tables, followed by an obvious SQL query calling this function:

```sql
function count_tables returns number
begin
<xsl:template match="/"
    <xsl:value-of
        select="count(//table)"/>
</xsl:template>
end

select name from Views
where count_tables(def) =
(select max(count_tables(def))
from Views)
```

The first line declares the XSLT function in Meta-SQL; between `begin` and `end` one writes arbitrary XSLT code. Of course, in general, Meta-SQL allows multiple XSLT functions to be declared and called in the SQL query that follows the function declarations.

As a second example, suppose we are given a list Removed of names of tables that are going to be removed, and we want to know which views will become invalid after this removal because they mention one of these table names. To express this meta-query in Meta-SQL, we write:

```sql
function mentions_table
param tname string
returns string
begin
<xsl:param name="tname"/>
<xsl:template match="/"
    <xsl:if
test="/table[string(.)=$tname]">true</xsl:if>
</xsl:template>
end

select name from Views, Removed
where mentions_table(def,Removed.name) = 'true'
```

Note that, using the XSLT parameter mechanism already mentioned near the beginning of
this section, function `mentions_table` takes an extra parameter `tname` (of type string). Accordingly, in the SQL query, the function is called on two arguments: the XML input `def`, and the parameter `Removed.name`.

As a final example, suppose we are given a second view definitions table `Views2`, and for every view name that is listed in both views tables, we want a new definition that equals the union of the first definition and the second definition. To express this meta-query in Meta-SQL, we write:

```sql
function unite
param v2 xml
returns xml
begin
  <xsl:param name="v2"/>
  <xsl:template match="/">
    <union>
      <xsl:apply-templates/>
      <xsl:apply-templates select="$v2"/>
    </union>
  </xsl:template>
</xsl:template>
select name, unite(v.def,v2.def)
from Views v, Views2 v2
where v.name=v2.name
```

Note that function `unite` outputs XML, and again takes an extra parameter `v2`, now also of type XML.

### 3 XML variables and XML aggregation

The simple combination SQL + XSLT is already quite useful, but its full potential is only realized when we add a language construct that allows us to extract the subelements of an XML document. For example, the simple meta-query

```sql
give all pairs \((v,t)\), where \(v\) is a view name and \(t\) is a table name mentioned in the definition of view \(v\)
```

is otherwise not expressible.

We therefore add `XML variables` to SQL: while the standard SQL range variables range over the rows of a table, XML variables range over the subelements of an XML document. Like range variables, XML variables are bound in the from-clause, in a similar way variables are bound in OQL [5] and in XQuery [27]. More specifically, an XML variable \(x\) is bound in a from-clause using a construct of the following form:

```sql
x in y[e]
```

Here,

- \(y\) is a previously bound XML variable or a column reference, or an XSLT function call, of type XML; and

- \(e\) is an XPath expression [26] specifying which subelements of \(y\) we want \(x\) to range over.

A bound XML variable can appear in an SQL expression anywhere a column reference can.

For example, the meta-query quoted above can now be expressed as follows:

```sql
function string_value returns string
begin
end
select v.name, string_value(x)
from Views v, x in v.def[//table]
```

Note that the body of function `string_value` is empty; indeed, the empty XSLT program
does exactly what we want here, namely, to return the string value of an XML document (in this case, a **table** subelement).

As another example, suppose we are given a log table $Log$ with stored queries (in a column $Q$), and we want to identify “hot spots”: subqueries that occur as a subquery in at least ten different queries. To express this meta-query, we write:

```sql
select s
from Log l, s in l.Q
where s is query
group by s
having count(l.Q) >= 10
```

**XML aggregation** XML variables allow us to go from an XML document to a set of XML documents. Conversely, we want to be able to go from a set of XML documents to a single one. Thereto, we add a natural aggregate function on XML columns, called $CMB$ (for “combine”), also used by Shanmugasundaram et al [19]. Just like the result of the standard aggregate function $SUM$ on a list of numbers $x_1, \ldots, x_n$ is the sum $x_1 + \cdots + x_n$, the result of $CMB$ on a list of XML documents $d_1, \ldots, d_n$ is the combined XML document

$$
cmb
\begin{array}{c}
| \cdots \cdots \\
\end{array}
\begin{array}{c}
d_1 \quad \cdots \quad d_n
\end{array}
$$

So, the top-level element of $CMB(d_1, \ldots, d_n)$ is always labeled ‘$cmb$’, and has the documents $d_1, \ldots, d_n$ as its subelements.$^3$

As an example, suppose we are given a view definitions table $Views3$ similar to $Views$, except that the same view name may appear with multiple definitions. Suppose we want to ask the following meta-query: for each view name, give the Cartesian product of its definitions. Thereto, we first write an easy XSLT function $cartprod$ (see Appendix [B]) that transforms an input of the form $CMB(d_1, \ldots, d_n)$ into the document

```
query

select
from
wildcard
table-ref ... table-ref
d_1 \quad d_n
```

We then write:

```sql
select name, cartprod(CMB(def))
from Views3 group by name
```

As another example, recall the third example meta-query from the Introduction: view expansion in the log. To express this meta-query in Meta-SQL, we first write two auxiliary XSLT functions (see Appendix [B]):

- **pair**, taking a string parameter $s$, and transforming an input document $d$ into the document

```
pair
\begin{array}{c}
| \\
\end{array}
\begin{array}{c}
name \quad d
\end{array}
```

- **rewrite**, taking an XML parameter $p$ of the form

```
\begin{array}{c}
| \cdots \cdots \\
\end{array}
\begin{array}{c}
pair \quad \cdots \quad pair
\end{array}
```

```
\begin{array}{c}
| \cdots \cdots \\
\end{array}
\begin{array}{c}
name \quad \cdots \quad name
\end{array}
```

```
\begin{array}{c}
| \cdots \cdots \\
\end{array}
\begin{array}{c}
d_1 \quad \cdots \quad d_n
\end{array}
```

```
\begin{array}{c}
| \cdots \cdots \\
\end{array}
\begin{array}{c}
s_1 \quad \cdots \quad s_n
\end{array}
```

$^3$CMB is not commutative, so in the outcome of an XML aggregation, the particular order of the grouped documents is undetermined and will be implementation-dependent. Shanmugasundaram et al [19] consider an ordered version of CMB.
where $s_1, \ldots, s_n$ are different strings and $d_1, \ldots, d_n$ are arbitrary XML documents, and transforming an input query $q$ by replacing every occurrence of an element of the form
\[
\text{table}
\mid
s_i
\]
by a copy of $d_i$.

We then write:
\[
\text{select rewrite}(l.Q, (\text{select CMB(pair(def,name)) from Views}))
\text{from Log l}
\]

4 Semantical meta-querying

The language we have so far: SQL combined with XSLT, and enriched with XML variables and XML aggregation, gives us all the power we need for ad-hoc syntactical meta-querying. We now complete Meta-SQL so as to allow semantical meta-querying as well.

To this end, we add a function EVAL for dynamic evaluation of SQL queries. EVAL takes an SQL query (more correctly, its syntax tree in XML format) as input, and returns the table resulting from executing the query. A call to EVAL can appear in an SQL expression anywhere a table reference can; the resulting table can thus be ranged over by a standard range variable.

As an example, suppose we are given a table Customer with two attributes: custid of type string, and query of type XML. The table holds queries asked by customers to the catalogue of a store. Every query returns a table with attributes item, price, and possibly others. The following meta-query shows for every customer the maximum price of items he requested:
\[
\text{select custid, max(t.price) from Customer c, EVAL(c.query) t group by custid}
\]

EVAL is all we need, provided we have enough information about the output scheme of the stored queries we are evaluating. For example, in the previous meta-query, we are only interested in the price attribute, and we know that every stored query evaluates to a table that indeed has a price column. But what if we are given an arbitrary collection of stored queries without information about their output schemes? They could even all have different output schemes!

Such a situation neatly fits the genre known as “semistructured data” [1]: data that has a structure (scheme), but we do not know it, and it can be irregular. Since XML is the standard format for semistructured data, and since we already have XML variables in Meta-SQL, we can easily solve the problem with an untyped version of EVAL. This UEVAL function works just like EVAL, except that the table resulting from the dynamic evaluation of the query is presented as a set of XML documents.

More concretely, suppose a particular stored query evaluates to a table with attributes $(A, B, C)$. Then every output row $(a, b, c)$ is represented as the XML document
\[
\text{row}
\mid
\begin{array}{ccc}
A & B & C \\
| & | & |
\end{array}
\mid
\begin{array}{ccc}
a & b & c \\
| & | & |
\end{array}
\]
The resulting set of XML documents is ranged over by an XML variable rather than a standard range variable; this is a new use we make of XML variables in the Meta-SQL language.

As a simple example, recall the second example meta-query from the Introduction: “which queries in the log return an empty answer?” To express this meta-query, we write:
select Q from Log l
where not exists
  (select x from x in UEVAL(l.Q))

Note that x is an XML variable, whereas t in the previous example is a standard SQL range variable.

The fourth example meta-query from the Introduction (query comparison after view expansion) is equally easy to express, given that we already saw how to express view expansion in the previous section. In particular, note that we can apply EVAL and UEVAL not only to queries directly stored in the database, but also to queries coming from a syntactical meta-subquery (such as view expansion).

Run-time errors  Both EVAL and UEVAL expect their input to be (the XML syntax tree of) a correct SQL query. If that is not the case, we consider this to be a programming error, and a run-time exception will be raised. Moreover an application of EVAL can still fail even if its argument is a correct SQL query, namely, when the query result does not have the expected columns.

Designing a meta-query language where dynamic evaluation of stored queries is statically typed so as to be safe from such run-time errors is possible [18], but leads to an overly restricted formalism. In the design of Meta-SQL, we have opted to prefer flexibility and expressive power above static typing.

5  Implementation

Meta-SQL is entirely compatible with modern SQL implementations offered by contemporary extensible database systems. Extensible (also called object-relational, or universal) database systems [21] support user-defined data types for the columns of tables, and allow user-defined functions on these types to be called within SQL. Extensibility is now part of the new SQL:1999 standard, and the major commercial vendors are aggressively moving to support it.

In Figure 2 we illustrate the architecture of an implementation of Meta-SQL, explained in more detail in this section.

Implementing XML columns  To support XML columns, it suffices to define a data type ‘XML’. We could derive this type from the built-in type CLOB (Character Large Object) and store XML documents as texts, but we could also derive from BLOB (Binary Large Object) and store XML documents as binary encodings of their DOM tree structures.

Implementing XSLT calls  Starting from Meta-SQL source code, consisting of a number of XSLT functions, followed by an SQL query using these functions, the Meta-SQL compiler does the following automatically:

1. For each XSLT function, we generate a wrapper function (in an external programming language such as C or Java) that invokes an XSLT processor, thus performing the required XSLT transformation on the arguments, and returns the result. If necessary, this result is converted to an SQL datatype like number or string.

2. All wrapper functions are compiled and put together in an object library.

3. Every wrapper function is registered in the database system (using SQL:1999 CREATE FUNCTION statements).

4. With the functions in place, the final Meta-SQL query can now be executed literally by the database system.
Almost all available XSLT processors provide an interface to various programming languages, and can be loaded together with the application that invokes them. Hence, the compiled wrapper functions can be loaded into the database server together with the XSLT processor functionality and executed as efficiently as possible.

**Implementing XML variables** Now the first and the last step in the above plan become more involved: in the first step, we must generate an additional function `EXTRACT`; in the last step, we must perform some rewriting on the SQL query. We next explain this in a bit more detail.

To support the XSLT calls, we needed only single-valued external functions: they return as output only a single value, be it a string, a number, or an XML document. To support XML variables, however, we need a set-valued external function. Specifically, the Meta-SQL system provides a function `EXTRACT`, which takes an XML document \( y \) and an XPath expression \( e \) as input, and which returns the set of all subelements of \( y \) that satisfy \( e \). This set is returned as a one-column table with attribute name `result`.

Every XML variable binding, say, \( x \) in \( y[e] \), is now rewritten by the Meta-SQL compiler into a call `EXTRACT(\( y, \ 'e' \))`. This call returns a table to which \( x \) is again bound, but now \( x \) has become a standard SQL range variable over the single attribute `result`.

For example, recall the first example of Section 3:

```sql
select v.name, string_value(x)
from Views v, x in v.def[/table]
```

This query will be rewritten as follows:

```sql
select v.name, string_value(x.result)
from Views v,
     table(EXTRACT(v.def,'/table')) x
```

The above from-clause contains two table expressions. Note that the variable ranging over the first table expression, namely \( v \), is directly used in the second table expression. This is an instance of what SQL:1999 calls a “lateral derived table” \([16]\). Such lateral joins were not allowed in SQL-92; we see that they are crucial here. We point out that they were present in OQL from the outset \([5]\).
Implementing EVAL and UEVAL  The function UEVAL can, like EXTRACT, be realized as a set-valued external function. This evaluation function takes an SQL syntax tree in XML as input; unparses it; sends the SQL query to the database; receives the answer rows; transforms them into XML as explained in the previous section; and returns the results. The XML variable ranging over the UEVAL result is handled in the same way as above.

For example,

\[
\text{select } Q \text{ from Log } l \\
\text{where not exists} \\
(\text{select } x \text{ from } x \text{ in UEVAL}(l.Q))
\]

is compiled into

\[
\text{select } Q \text{ from Log } l \\
\text{where not exists} \\
(\text{select } x.\text{result} \\
\text{from } \text{table(UEVAL}(l.Q)) \text{ } x)
\]

The implementation of EVAL is a bit more complicated, because EVAL returns not a set of XML documents, but a normal SQL table ranged over by a standard range variable. In this case, the Meta-SQL compiler first determines the specific attributes that are mentioned in connection with this range variable. A specific table-valued external function having this set of attributes as output scheme is then generated and registered in the database system. This evaluation function will actually not send its exact argument SQL query to the database for evaluation, but rather its projection on the output scheme in question.

For example, recall the first example of Section 4

\[
\text{select custid, max(t.price) } \\
\text{from Customer } c, \text{ EVAL}(c.query) \text{ t} \\
\text{group by custid}
\]

To implement this query, the Meta-SQL system will generate an evaluation function, say, EVAL\_1, with output scheme \((\text{price})\), and will rewrite the query to

\[
\text{select custid, max(t.price)} \\
\text{from Customer } c, \\
\text{table(EVAL\_1(c.query)) t} \\
\text{group by custid}
\]

Here, EVAL\_1(q), when called on any stored query q, evaluates and returns the projection \(\pi_{\text{price}}(q)\).

If the select-clause would have additionally included \(\text{sum(t.qty)}\), then the system would have generated a different evaluation function EVAL\_2 with output scheme \((\text{price,qty})\) and according behavior.

Implementing XML aggregation  The XML aggregate function CMB introduced in Section 3 can be directly provided as a user-defined aggregate function.

A working prototype  We have developed a prototype implementation on top of DB2 UDB \[3\], which we chose because it is freely available to university research and teaching.

We implement the external XSLT wrapper functions in Java, in conjunction with the popular and free Java-based XSLT processor SAXON \[12\]. SAXON also provides a convenient Java-XML interface making the EXTRACT function very easy to write.\(^4\) A caveat in connection to the implementation of EVAL and UEVAL is that DB2 UDB currently does not allow SQL calls inside external functions. We bypass this restriction by spawning a child process, which then makes a new connection to the database in order to evaluate the stored query.

\(^4\)IBM provides an ‘XML Extender’ to DB2 UDB which already provides an XML data type (derived from CLOB as we do), but with insufficient functionality for our needs. For example, there is also an Extract function, but it is much weaker than the EXTRACT function we need to implement our mechanism of XML variables.
6 Experimental performance evaluation

In this section we describe some performance experiments on our prototype implementation. Unless stated otherwise, the results shown are averages of multiple executions of the test under discussion.

Java Overhead Our first test measures the overhead implied by calling external functions written in Java. To that cause we created three simple single-valued external functions, CST, MUL and CAP, which respectively return a constant number, multiply a number with a constant, and transform the input string to capital letters. The following four queries were executed:

select * from T
select CST(A), B from T
select MUL(A), B from T
select A, CAP(B) from T

Here, T consists of an integer column A and a character column B. The first query is executed to measure the time needed to select tuples from T without calling an external function.

Figure 3 shows the results for varying table sizes. As was to be expected, the running times of all functions grow linearly in the number of input tuples. Since the time needed to execute the last three queries closely resembles that of the first, we may conclude that there is a minimal overhead involved with external functions programmed in Java.

XSLT Processor overhead Our prototype implements XSLT functions by external wrapper functions calling the SAXON XSLT processor. To measure the startup cost of the XSLT processor, we compared the Meta-SQL query function XSLT_CST returns number

begin
    <xsl:template match="/">
        40513
    </xsl:template>
end

select XSLT_CST(A) from T

whose execution time is dominated by starting up the XSLT processor, with the query

select CST(A) from T

Here, CST is single-valued external function which also returns the same constant on all inputs. Table T consists of a single XML column, whose values are single-node trees.

Figure 4 shows the results for varying table sizes. The XSLT function running time is significantly larger than that of CST, and grows linearly in the number of input tuples, which indicates that there is a constant startup cost imposed by the XSLT processor. As such, a Meta-SQL implementation would greatly benefit from more efficient XSLT/XML processors.

A valid question to ask next is how the size of the input XML document affects the running time of an XSLT function. To this cause we compared the following two queries:

select XSLT_COPY(A) from T1
select COPY(A) from T1

Here, both XSLT_COPY and COPY copy their input to the output. The only difference is that XSLT function XSLT_COPY does so by XSLT template matching whereas external function COPY performs a true copy. Table T1 consists of a single XML column A.

Figure 5 shows the running times of these queries on tables with 1000 documents, for varying document sizes. Both running times grow linearly when the number of nodes per
Figure 3: Performance of external functions in Java

Figure 4: Performance of XSLT calls
tuple increases, as was to be expected. Combined with the previous results, this indicates that calling a XSLT function has a rather large start-up cost, but a relatively small execution cost.

**Extract** As described in the Section 5, XML variables are implemented by a set-valued external function called **EXTRACT**. To see how set-valued external functions compare with single valued functions, we created a single-valued function named **SCALAR_EXTRACT**, which evaluates the XPath expression / on its input, and executed the following three queries:

```sql
select x from T, x in B[//*]
select x from T1, x in B[/*]
select SCALAR_EXTRACT(B) from T1
```

Here, T consists of an XML column B, which is populated by 1000 documents of m nodes. Table T1 contains the result of the first query. Hence, the second and third query return the same output as the first; here, the second query still uses an XML variable, whereas the third query makes a direct function call. The difference is that **EXTRACT** is called 1000 times in the first query, each time returning m tuples, whereas in the second and third query **EXTRACT** and **SCALAR_EXTRACT** are called m × 1000 times, each call returning a single tuple. Thus, this test compares the overheads involved with set-valued functions returning multiple tuples, set-valued functions returning a single tuple, and single-valued functions returning a single tuple.

We timed the execution for varying m, as shown in Figure 6. Due to the large running times, the test was only timed once.

We can safely conclude that returning multiple tuples from a set-valued function is not a problem. Indeed, the running time of the first query is quite reasonable and increases linearly with m (although it appears constant in Figure 6 due to the large running times of the other queries). In particular, it is multiple times faster than returning m times a single tuple. As such, the implementation of XML variables in our approach performs very reasonably.

Since both **EXTRACT** and **SCALAR_EXTRACT** use the XSLT processor to evaluate their XPath expressions and because the running time of the second query resembles that of the third, we can also conclude that the overhead of a set-valued external function is about the same as that of a single-valued one.

With the following two queries, we measure the overhead of an **EXTRACT** call versus the actual amount of work that needs to be done:

```sql
select x from T, x in B[//*]
select C from T, T2
```

Here, T is as before and T2 is the table with XML column C, containing the result of the first query on a single document in T. Since all documents in T are the same, both queries return the same result. By adding the time the XSLT processor needs to evaluate the XPath expression //* 1000 times to the timing of the second query, we get an estimate of the time needed to calculate the result of the first query, without actually calling **EXTRACT**.

As can be seen from Figure 7, the running time of both queries grow linearly in their input. However, the first query outperforms the second one when m grows larger. Hence, although **EXTRACT** has some startup overhead, it is efficient when applied to large documents. Indeed, it even outperforms a setting in which the same amount of work needs to be done, but no call to a set-valued external function is made. Combined with our previous results, this shows that XML variables are efficiently implementable.
Figure 5: Performance of XSLT calls

Figure 6: Performance of Extract—Experiment 1
Eval Remember from Section 5 that EVAL and UEVAL are implemented as set-valued external functions which create a subprocess to execute their input query. In order to measure the overhead incurred by starting this process and communicating with it, we created tables T and T’ with integer column A and XML column B. Every tuple in T contains in its B column the following query in XML format:

\[
\text{select } * \text{ from T1}
\]

We then measured the time needed to execute the query

\[
\text{select A, e.A from T, EVAL(T.B) as e}
\]

Furthermore, with n be the number of tuples in T, we timed the execution of n times the query

\[
\text{select * from T1}
\]

(in Java, since EVAL uses Java to execute its queries) and added that to the time needed to compute the same result:

\[
\text{select T.A, T1.A from T, T1}
\]

Comparison of these two measurements gives a good indication of the overhead implied by EVAL.

As shown in Figure 7, calling the EVAL function is six to seven times slower than preprocessing and joining, and grows linearly in the number of input tuples.

Conclusion The experiments above indicate that our proposal for implementing meta-querying features on top of the database engine induces constant, predictable overheads, which is certainly good news.

Still, the running times are sometimes too high. Therefore, more efficient XSLT processors would certainly help. The ideal solution
would be to incorporate XSLT processing directly into the query processor, as has recently been suggested by Moerkotte [17]. It would also help if we could implement the EVAL and UEVAL functions entirely in a programmed SQL language such as Oracle’s PL/SQL, or SQL/PSM, in which case the overhead of calling a table function and starting a subprocess could be avoided.

On the other hand, our current implementation method has the advantage that it is generally applicable without a need to change the internal query processor (which is often not feasible).

7 Discussion

Other meta-query languages. Meta-SQL is the first practical language for meta-querying. At the same time, however, it is firmly based on our past experience in designing formalisms for meta-querying. More specifically, two of us (in collaboration with Neven and Van Gucht) have earlier introduced the reflective relational algebra [24] and the meta relational algebra [18], two formal meta-query languages based on the relational algebra rather than on SQL. The two formalisms differ in their approach: the reflective algebra is untyped, stores queries in so-called “program relations”, and uses the basic relational algebra operators for the syntactical manipulation; in contrast, the meta algebra is statically typed and views stored queries as an abstract data type with specific operations for syntactical manipulation. Meta-SQL is the practical culmination of these two proposals, and stands in between the two approaches: like the meta algebra, it stores queries in an XML abstract data type, but like the reflective algebra, it is essentially untyped. Every meta-query expressed in the reflective rela-
tional algebra, or in the meta relational algebra, can also be expressed in Meta-SQL.

**Schema querying.** Starting with the seminal paper on HiLog [4], the concept of schema querying has received considerable attention in the literature. Clearly, schema querying is a special kind of meta-querying. For instance, SchemaSQL [14] augments SQL with generic variables ranging over table names, rows, and column names. It is not difficult to simulate SchemaSQL in Meta-SQL, using XML variables and UEVAL calls. Of course, since SchemaSQL is more specialized, it allows more opportunities for optimized implementation [15].

**Commercial XML extensions.** All the major commercial ORDBMS vendors are providing XML extensions to their products, However, the emphasis there is mainly on publishing results of SQL queries in XML format (e.g., [19, 11]), so that they can be further processed using the standard XML tools, including XSLT. This combination of SQL and XSLT is clearly quite different in scope compared to the combination we have proposed in this paper. The other direction, where large XML documents are decomposed and stored in tabular format, has also been researched (e.g., [20, 7]) and is getting into the commercial products.

We also mention that several features of "SQL/XML" [9, 10] such as the XML data type and the mapping of tables to XML values are similar to those found in this paper. Moreover, an Extract-like operator and functions operating on XML values (albeit through XQuery) are listed among the future work.

**Text extensions.** Given that most database systems now support a text data type with better functions for text searching and editing than standard SQL, one may wonder why we cannot support meta-querying simply by representing the stored queries as text. The answer is that for many meta-queries the structure of the stored queries is important. For example, searching for the use of a certain view name in a query is more than a simple pattern search. Using syntax trees and XSLT makes structural querying very easy.

**XML query languages.** Although the focus of this paper has been on meta-querying as opposed to general XML querying, we still would like to conclude by pointing out that Meta-SQL, without EVAL, is not only a language for syntactical meta-querying, but can serve in general as a query language for databases containing XML documents in addition to ordinary relational data. Its closeness to standard SQL and object-relational processing is a major advantage. On the other hand, the treatment of XML documents as abstract data items seems less appropriate for "pure" XML databases, i.e., huge XML documents. However, as already indicated above, there seems to be a strong trend in the database processing world to decompose such XML databases into relational data anyway.

**Acknowledgment** We are indebted to Frank Neven and Dirk Van Gucht for inspiring conversations. We also thank our students Igor Kalders, Frank Pilgrim, and Jef Vos for their help with the prototype implementation.
