An Update on Preoperative Radiotherapy for Locally Advanced Rectal Cancer

Seung-Gu Yeo, Dae Yong Kim

INTRODUCTION

In contrast to colon cancer, several features make the successful management of rectal cancer clinically challenging. The absence of a serosal barrier permits early tumor extension into the perirectal tissues. The rectum also lies close to vital, and sometimes unrespectable, pelvic structures (e.g., the bladder, ureters, iliac vessels, and the sacrum). The compact nature of the mesorectum within the confines of the pelvis complicates the adequate removal of all mesenteric nodes at risk for metastatic disease [1]. Due to these specific characteristics of rectal cancer, surgery alone has been associated historically with local recurrence in up to one in four patients. Locally recurrent disease is usually incurable and causes profound morbidity, suffering, and death. Subsequent adjuvant randomized trials evaluated different combinations of radiation therapy (RT) and 5-fluorouracil-based chemotherapy. These studies showed that postoperative chemoradiotherapy (CRT) improved survival and local control relative to surgery alone, leading to the standard implementation of these therapies for locally-advanced rectal cancer (LARC) by the 1990s [2, 3].

Because of the potential benefits associated with preoperative therapy, interest has evolved in adopting this approach in rectal cancer patients. A randomized trial from Europe proved that by simply altering the sequence of CRT, improved rates of local control, treatment compliance, and acute and late toxicity could be achieved, leading to a new paradigm of care [4]. Parallel to this paradigm shift in treatment sequence, diverse CRT responses among patients can be identified earlier in surgical specimens whereas these responses could only have been identified after long-term follow-up when CRT was provided postoperatively. Accordingly, several questions have newly emerged regarding these diverse pathologic CRT responses: Can a good pathologic CRT response be an early indicator of good prognosis? How can we define the criteria for a good pathologic CRT response? Can we predict a good...
pathologic CRT response before surgery or before preoperative CRT? Following preoperative CRT, is less invasive or less radical surgery feasible for patients with a good CRT response? Herein, we review these questions that are confronted in the preoperative CRT approach for patients with LARC.

**PREOPERATIVE CRT**

Preoperative RT has been shown to significantly decrease the local recurrence rate and improve survival, provided that a biologically equivalent dose of at least 30 Gy is administered [5]. The potential advantages of preoperative over postoperative RT include enhanced effectiveness in well-oxygenated tissue, a damaging effect on cells that may be spread locally or distantly at the time of resection, downstaging of advanced tumors, and better treatment compliance [6]. This theoretical superiority of the preoperative approach over postoperative adjuvant therapy has been confirmed in the German rectal cancer trial (CAO/ARO/AIO 94 trial) [4]. This trial randomly assigned more than 800 patients with cT3–4 or cN+ rectal cancer to two different CRT sequence strategies. Compared with postoperative therapy, patients who received preoperative therapy had a significantly lower incidences of local recurrence (15% vs. 6%, \( P = 0.006 \)), acute toxicity (40% vs. 27%, \( P = 0.001 \)) and chronic toxicity (24% vs. 14%, \( P = 0.012 \)), a higher incidence of sphincter preservation (20% vs. 39%, \( P = 0.005 \)), and no difference in 5-year overall survival (OS; 76% vs. 74%). The CAO/ARO/AIO 94 trial remains the definitive trial in CRT for rectal cancer.

Although the results must be interpreted cautiously due to the trial’s limitations, other studies comparing the two different CRT sequences have reported improved disease-free survival (DFS) with no difference in local control [7, 8]. The National Surgical Adjuvant Breast and Bowel Project R-03 study [7] had limitations regarding premature closure of the trial due to insufficient accrual and used different chemotherapy regimens and surgical techniques compared with the CAO/ARO/AIO 94 trial. However, patients with LARC who received preoperative therapy showed a significant improvement in 5-year DFS compared with those who received postoperative therapy (65% vs. 53%, \( P = 0.011 \)). Local recurrence rates did not differ (11%) between the preoperative and the postoperative approaches. Similar outcomes were reported by Yeo et al. [8], although their study was also limited by its retrospective nature. They analyzed 487 patients with cT3 mid or distal rectal cancer who had received preoperative or postoperative CRT. The 5-year local-recurrence-free survival rate was not different, 95.3% and 92.1% in the preoperative and the postoperative CRT groups, respectively (\( P = 0.402 \)); however, the 5-year DFS rate of 78.8% in the preoperative CRT group was significantly better than that of 63.0% in the postoperative CRT group (\( P = 0.002 \)).

During the same period, similar to improvements in adjuvant treatments, improvements in surgical techniques have dramatically lowered the incidence of local recurrence in rectal cancer. Careful pathological studies have clearly demonstrated that the major cause of local recurrence is the persistence of tumor foci within the mesorectum [9]. Intact removal of the entire mesorectum (total mesorectal excision, TME) in cancers of the mid or lower third of the rectum was pioneered by Heald et al. [10] and has resulted in local recurrence rates lower than 5-10%.

However, the effect of preoperative RT on the local recurrence rate was consistent even when the optimal surgical technique (TME) was implemented. This was demonstrated by the results of a Dutch rectal cancer trial that randomized 1,861 rectal cancer patients to undergo either RT followed by TME or TME alone in the setting of a national surgical training program [11]. Compared with TME alone, a short-course (5 Gy × 5 fractions) of RT followed by TME within a week resulted in a significantly lower local recurrence rate, although no improvement in OS was noted. The 10-year cumulative incidence of local recurrence was 5% in the group assigned to RT and surgery and 11% in the surgery-alone group (\( P < 0.0001 \)); i.e., preoperative RT reduced the 10-year local recurrence by more than 50% relative to surgery alone [11]. A similar benefit in local control with preoperative RT combined with TME was shown by a Medical Research Council trial, which evaluated routine preoperative short-course RT versus selected (restricted to patients with involvement of the circumferential resection margin) postoperative CRT [12].

The trials from the European Organization for Research and Treatment of Cancer and Fédération Francophone de la Cancérologie Digestive have supported the results of previous trials, finding that improved pathologic complete response rates and local control can be achieved with the addition of chemotherapy to long-course RT, although the survival impact of concurrent chemotherapy in a preoperative approach remains uncertain [13, 14].

**PROGNOSTIC SIGNIFICANCE OF A PATHOLOGIC CRT RESPONSE**

In the postoperative CRT era, tumor response to CRT could be determined after long-term follow-up; however, if preoperative CRT is employed, tumor response can be assessed much earlier in the surgical specimen. For most patients, preoperative CRT results in clinically meaningful tumor regression, but the degree of response varies among patients: some show almost no response whereas others exhibit a pathologic complete response (ypCR). The ypCR with absence of viable tumor cells in the surgical specimen occurs in approximately 10-30% of LARC patients. Although some studies have reported no improvement in outcomes for patients with ypCR [15], many have suggested that ypCR is associated with a favorable outcome regarding local control, distant recurrence, DFS, and OS [16-18]. One explanation for the good prognosis after ypCR is that ypCR is indicative of a prognostically favorable biological tumor profile, with lower propensity for local recurrence and distant metastases and better survival than for patients showing a lesser response. The Korean Radiation Oncology Group (KROG 09-01) collected
clinical data for 333 LARC patients with ypT0Nany following preoperative CRT and curative radical resections between 1993 and 2007 [17]. After a median follow-up of 43 months, the 5-year DFS was 84.6% and OS was 92.8%. Excluding 29 patients (8.7%) with ypT0N+ disease, the 5-year DFS and OS were 88.5% and 94.8%, respectively, in 304 ypT0N0 patients. Similarly, an Italian group reported the prognostic value of ypCR in a study of 566 ypT0N0 patients from 36 centers [16]. After a median follow-up of 46 months, pelvic relapse and distant metastasis occurred in 1.6% and 8.9%, respectively. The 5-year DFS, OS, and cancer-specific survival rates were 85%, 90%, and 94%, respectively. These studies showed that LARC patients achieving ypT0N0 status after preoperative CRT had favorable long-term outcomes.

Favorable outcomes for ypCR patients were evident when compared with a control group with residual disease. Maas et al. [18] performed a pooled analysis of individual patient data from several study centers, and 484 (15.6%) of 3,105 patients showed ypCR. The median follow-up for all patients was 48 months, and the 5-year crude DFS was 83.3% for patients with ypCR and 65.6% for those without ypCR (P < 0.0001). The adjusted hazard ratio for ypCR for failure was 0.54 (95% confidence interval, 0.40-0.73), indicating that patients with ypCR had a significantly increased probability of DFS. The effect of ypCR on long-term outcome was not affected or modified by clinical T or N category, administration of postoperative chemotherapy, distance from the anal verge, or type of surgery.

**CRITERIA FOR GOOD RESPONSE**

The data indicate that pathologically assessed tumor response to preoperative therapy can be a short-term treatment response indicator and a surrogate marker of long-term outcome. Accordingly, novel preoperative treatments may be compared with benchmarks of response-stratified outcomes. Knowledge of such benchmarks may also be useful for clinicians to develop subsequent treatments allowing risk-adapted strategies. However, some discussion is necessary regarding the criteria of benchmarks, namely, good pathologic response: Does ypCR include complete response in the primary tumor only (ypT0Nany) or should it be restricted to ypT0N0? Is there a prognostic difference between ypCR and minimal residual disease?

The ypN status in LARC patients receiving preoperative CRT demonstrated major prognostic importance. Among the four factors (ypT, ypN, ypStage, and Dworak’s tumor regression grade [TRG]), which were found to be significant predictors of DFS in a multivariate analysis, ypN status was the most discriminatory factor predicting DFS, followed by ypStage, ypT, and finally TRG [19]. Another study similarly reported that the ypN classification was the most significant factor independently predicting the OS of LARC patients [20]. The equally important prognostic significance of ypN status was also found in selected patients with ypT0 status. In the KROG 09-01 study [17], ypN status was ypT0N0 in 304 patients (91.3%), ypT0N1 in 22 patients (6.6%), and ypT0N2 in 7 patients (2.1%). A patient’s ypN status was revealed to be the most relevant independent prognostic factor for both DFS and OS in 333 ypT0 patients: 5-year DFS rates were 88.5%, 51.9%, and 21.4%, and the 5-year OS rates were 94.8%, 76.2%, and 64.3% in ypT0N0, ypT0N1, and ypT0N2 patients, respectively (P < 0.001 for both). ypT0N+ patients constitute a very small proportion of the ypT0 group; thus, they may not change to any great degree the favorable outcomes of ypT0Nany patients. However, patients with ypT0N+ disease were in a separate group with a distinctly unfavorable prognosis, so the criteria of good pathologic response need to be restricted to ypT0N0 status [21].

When the most important prognostic factor in LARC receiving preoperative CRT, the ypN status, is the same as the ypN0 status, minimal residual disease in the primary tumor (ypT1-2N0) may not confer a significantly different prognosis compared with ypT0N0 status. Moon et al. [22] showed that patients with ypT0N0, ypT1N0, and ypT2N0 cancers demonstrated no significant difference in 5-year OS (ypT0N0, 96.5%; ypT1N0, 95.7%; ypT2N0, 92.4%; P = 0.497) or 5-year DFS (ypT0N0, 90.2%; ypT1N0, 100%; ypT2N0, 89.3%; P = 0.205). In terms of ypStage, the 5-year OS (ypStage 0, 96.5%; ypStage I, 92.9%; P = 0.346) and 5-year DFS (ypStage 0, 90.2%; ypStage I, 90.7%; P = 0.879) were no better in patients with ypStage 0 tumors than in those with ypStage I tumors. The authors insisted that a suitable endpoint representing a good pathologic CRT response would be a grouping that combines ypStage 0 and ypStage I (ypT0-2N0M0).

In a stage-to-stage (ypStage vs. pStage) comparative analysis that demonstrated better DFS after preoperative CRT compared with postoperative CRT for cT3 rectal cancer patients [8], preoperative CRT yielded a downstaging to ypStage 0-I in 155 patients (42.6%), and this downstaged group showed a significantly improved DFS compared not only with ypStage II but also with pStage II patients with postoperative CRT. Post-CRT ypStage 0-I patients revealed outcomes that were nearly identical to the historical results for pStage I rectal cancer without postoperative treatment. The ypStages II and III, in which patients with and without CRT responses in the primary tumor and/or mesorectal lymph nodes were combined, demonstrated DFSs that were similar to those for pStages II and III, respectively. Thus, the existence of ypStage 0-I patients was suggested to be the cause of the improved DFS observed in the preoperative CRT group.

**PREDICTION OF GOOD RESPONSE**

In contrast to postoperative treatments that can be modified based on pathologic CRT response information, markers predicting CRT response are necessary to implement risk-adapted strategies in preoperative treatment and surgery. More aggressive preoperative regimens may be considered in patients who are less likely to respond to standard preoperative therapy. Conversely, sphincter-sparing surgical procedures or tumor-localized resections may be an
Fig. 1. Schematic diagram of multimodality treatments for patients with locally advanced rectal cancer (LARC). Conventional treatments for LARC consisted of preoperative chemoradiotherapy (CRT), radical surgery, and postoperative chemotherapy (CT). When the pathologic CRT response reliably predicting long-term outcomes can be accurately determined before surgery or before CRT, then selected patients with good or poor CRT response may be recommended for less or more intensified treatments, respectively, rather than conventional treatments. Pre-op, preoperative; Post-op, postoperative.

Clinical factors
Carcinoembryonic antigen (CEA) has been shown to inhibit cell death by causing a loss of anchorage to the extracellular matrix [23]. Tumor cells containing a high density of CEA may resist radiation-induced changes that occur using either a pro-apoptotic or pro-survival molecular pathway. Yoon et al. [24] investigated pre-CRT clinical parameters that could predict CRT response in LARC. Multivariate analysis revealed the following: predictors of T-level downstaging (ypT0-2) included pretreatment hemoglobin level, cN0 classification, and serum CEA level; predictors of tumor regression (TRG 3-4) included cN0 classification and CEA level; and the predictor of complete regression was the CEA level. The authors suggested that the pre-CRT CEA level (≤5 ng/mL vs. >5 ng/mL) was the most important clinical predictor of pathologic tumor response. Furthermore, Park et al. [25] analyzed changes in the ratios of tumor response with increasing CEA levels in LARC. The rates of good response (TRG 3-4) decreased significantly as the pre-CRT CEA levels became more elevated (CEA, ng/mL: ≤3, 36.4%; 3-6, 23.6%; 6-9, 15.6%; >9, 7.8%; P < 0.001), revealing a linear inverse correlation between pre-CRT CEA levels and tumor response.

Hypoxia is associated with resistance to RT. Tumor oxygenation is affected by several factors, such as adequacy of blood supply, microcirculation, and the oxygen-carrying capacity of the blood, which is expressed as the hemoglobin level. Lee et al. [26] reported that tumor response rates in LARC were significantly different below and above a hemoglobin level of 9.0 g/dL. Favorable tumor response (TRG 3-4) was shown in 29% of patients with hemoglobin levels ≥9.0 g/dL, but in no patient with a hemoglobin level <9.0 g/dL. Additionally, no difference was observed in tumor response between the non-transfusion and the transfusion groups of patients with hemoglobin levels ≥9.0 g/dL. The authors suggested that pre-CRT anemia is an indicator of poor response to preoperative CRT and that transfusion may improve its therapeutic efficacy.

Molecular markers
Studies on molecular biomarkers for predicting the response to preoperative CRT in rectal cancer have focused on tumor suppressor genes (p53, p21), apoptotic factors (Bcl-2, Bax), epidermal growth factor receptor, cyclooxygenase-2 (COX-2), and vascular endothelial growth factor, or on microarray gene expression analysis displaying complete genomic patterns [27]. Bax is a pro-apoptotic protein, and its expression induces mitochondrial permeability, which leads to release of cytochrome c and initiation of a signaling cascade promoting DNA degradation and cell death. Bax expression in rectal tumors was found to be significantly higher in the post-CRT complete response group than in the partial response group (54% vs. 29%, P = 0.017) [28]. Overexpression of COX-2 in pretreatment rectal tumors was shown to be predictive of poor tumor regression after preoperative CRT, and a clinical trial of COX-2 inhibitors for patients with COX-2 overexpression was suggested to improve the response rate of preoperative CRT [29].

A single molecular marker approach has limitations in therapeutic response prediction, and no single marker has yet been consistently identified as clinically applicable in rectal cancer. By contrast, microarray gene expression analysis, which enables the display of complete genome patterns at one time, may be more promising. Kim et al. [30] obtained tumor tissues from 46 patients with rectal cancer (31 for training and 15 for validation testing). The 31 training samples comprised 20 partial CRT response and 11 complete CRT response cases. A primary set of 261 genes was identified as differentiating between partial and complete response. A gene set comprising the top-ranked 95 genes, displaying differential expression between partial and complete response, was applied to predict response to CRT. Complete response and partial response were accurately predicted in 84% (26/31) of the training samples and 87% (13/15) of the validation samples.
Imaging

The variability in tumor-size changes after preoperative CRT may represent an aspect of biologic tumor heterogeneity that can yield important information for prognostic prediction in LARC patients. However, irregular tumor shape and non-uniform treatment-related shrinkage make it difficult to identify all subtle tumor-size changes induced by CRT using traditional methods, which measure two-dimensional (World Health Organization) or only one-dimensional (Response Evaluation Criteria in Solid Tumors) maximal tumor diameters [31]. This challenge can be overcome by quantifying detailed changes in tumor volume using three-dimensional region-of-interest volumetry. Yeo et al. [32] measured tumor volume using three-dimensional region-of-interest volumetry based on magnetic resonance imaging (MRI) before and after preoperative CRT, but before surgery. They analyzed the correlation between the tumor volume reduction rate (TVRR) and the pathologic tumor response in 405 LARC patients. The mean TVRR was 65.0% ± 22.3% for all patients. TVRRs according to ypT classification (ypT0-T2 vs. ypT3-T4), ypN classification (ypN0 vs. ypN+), downstaging (ypStage 0-I vs. ypStage II-III), good regression (TRG 3-4 vs. TRG 1-2), and complete regression (TRG 4 vs. TRG 1-3) were all significantly different (P < 0.05). When the TVRR was categorized into three groups (<60%, 60-80%, and >80%), the rates of ypT0-T2, ypN0, downstaging, and good regression were all significantly greater for patients with TVRRs ≥60%, as was the complete regression rate for patients with TVRRs >80% (P < 0.05). In addition to its predictive value, this TVRR information also showed statistical significance as an independent prognostic factor for LARC patients [33]. Kang et al. [34] analyzed 84 LARC patients after similarly measuring the TVRR and reported that TVRR >75% was significantly associated with increased ypCR rate, but that TVRR did not show a significant association with ypT or ypN down-classification and TRG. However, they used a different definition of ypT down-classification (ypT lower than cT) and a different TRG grading system (Mandard’s).

Conventional imaging modalities have inherent limitations in assessing the response to preoperative CRT for rectal cancer due to post-radiation edema, inflammation, and fibrosis [35]. Instead, functional imaging techniques depict the metabolic and the microstructural characteristics of the tumor and can provide a deeper insight into the tumor’s biological property. In rectal cancer, two imaging techniques show great promise for response prediction during and after preoperative treatment: namely, 18F-fluorodeoxy glucose positron emission tomography-computed tomography (18F-FDG PET-CT) and diffusion-weighted MRI (DW-MRI). A significant reduction was noted in the standardized uptake value (SUV) on post-radiation PET of responders compared with non-responders [36]. However, 18F-FDG-PET has some limitations, such as spatial resolution and difficulty in differentiating between tumor and inflammation. Conversely, DW-MRI can differentiate persistent tumors from therapy-related inflammation or necrosis with a high specificity. Patients with a good response to treatment generally show a lower apparent diffusion coefficient (ADC) prior to treatment, with a higher change in ADC during and after CRT [37]. The hypothesis is that a low initial ADC value represents a more restrictive environment with less interstitial edema and necrosis and a higher cellularity. Necrosis is generally associated with an acidic environment and a low oxygen concentration that influences the response to CRT. Lambrecht et al. [38] explored combining the above two imaging modalities for determining the probability of ypCR after preoperative CRT in LARC. The authors postulated the existence of a predictive algorithm for ypCR with a sensitivity of 100% and a specificity of 94% by combining the optimal ΔSUV (max) thresholds during and after CRT or by combining the thresholds for the initial ADC value and the ΔSUV (max) during CRT. However, before these complex imaging techniques and consequent analyses can be implemented in daily practice, considerable effort towards standardization of protocols and analysis is necessary to ensure reproducibility of the results.

LOCAL EXCISION IN GOOD RESPONDERS

The mainstay of surgical therapy for LARC remains the low anterior resection or the abdominoperineal resection. Unfortunately, significant morbidity risks are associated with a radical resection, including frequent defecation, voiding problems, and sexual dysfunction. Furthermore, the lifestyle and the body image of patients who undergo an abdominoperineal resection are profoundly altered [1, 39]. Patients who either refuse abdominoperineal resection to preserve the anal sphincter or have pre-existing medical co-morbidities have led some physicians to advocate for local excision in selected rectal cancer cases. However, local excision does not surgically address the lymphatic tissue at risk within the mesorectum. Thus, tumors at high risk for lymphatic spread or clinically obvious nodal involvement would not be readily amenable to this approach. For this reason, indications for local excision have been highly restricted to tumors without factors associated with mesorectal lymph node metastasis, such as cT2-3, high grade, lymphovascular/perineural invasion, >3-4 cm in size, or >40% of the rectal wall circumference [1].

Significant tumor regression (downsizing and downstaging) following preoperative CRT may lead to the use of local excision as an alternative treatment option even in patients with the above risk factors. The key rationale for this approach is the correlation between radiosensitivity and the inherited low aggressiveness of rectal cancer, and the correlation between the radiosensitivity of the primary tumor and that of the mesorectal nodal disease [40]. Read et al. [41] analyzed 644 patients with rectal cancer receiving preoperative RT/CRT and a proctectomy. The ypN+ rate was 2% in ypT0, 4% in ypT1, 23% in ypT2, 47% in ypT3, and 48% in ypT4 patients. The authors suggested that it was reasonable to select ypT0-1 for local excision and to reserve a proctectomy for patients who demonstrated residual ypT2-4 disease. Kim et al. [42] reported that ypT classification was the most reliable predictor of
ypN status in a multivariate analysis including 282 LARC patients. The ypN+ rate was 3.4% in ypT0-1, 16.9% in ypT2, and 49.3% in ypT3 patients.

A prospective randomized study was undertaken to compare the oncologic results for local excision via transanal endoscopic microsurgery and those for laparoscopic TME in the treatment of cT2N0 rectal cancer following preoperative CRT [43]. Seventy patients were enrolled, and after a median follow-up of 84 months, both treatment groups demonstrated similar results in terms of local recurrences, distant metastases, and probability of survival. Yeo et al. [44] reported the outcomes of 11 patients with cT3 distal rectal cancer who received a local excision following preoperative CRT between 2003 and 2008. Local excision was recommended for patients who met all of the following criteria: 1) refusal of radical surgery or no acceptance of anal ablation, 2) initial cT3 classification, 3) clinically complete remission or minimal residual, and 4) full recognition of risks for local excision. The ypT0 was observed in eight patients, ypT1 in two patients, and ypT2 in one patient. After a median follow-up of 59 months, the 5-year local-recurrence-free survival, DFS, and OS rates were 90.9%, 81.8%, and 88.9%, respectively. No grade 3 or worse gastrointestinal toxicity was detected. Immediate radical surgery was strongly recommended for a patient with ypT2, but he refused and died of distant metastasis. The authors suggest that full-thickness local excision following CRT may be an acceptable option for cT3 distal rectal cancer that responds well to CRT. The M. D. Anderson Cancer Center performed a retrospective review of patients who underwent preoperative CRT followed by surgery for cT3 rectal cancer [45]. Forty-seven patients underwent local excision, and 473 patients underwent TME. Twenty-three (49%) local excision patients had a complete response to CRT, 17 (36%) had microscopic residual disease, and 7 (15%) had gross residual disease, compared with 108 (23%), 89 (19%), and 276 (58%) TME patients, respectively. No significant difference was noted between the 10-year actuarial local recurrence rate for the local excision group versus the TME group (10.6% and 7.6%, respectively; P = 0.52). The DFS, disease-specific survival, or OS rates also did not differ between the two groups. This study indicated that, in selected patients with cT3 rectal cancer who demonstrated an excellent response to preoperative CRT, full-thickness local excision offered outcomes comparable to those achieved with TME.

However, before the option of surgical conservation can be offered safely to patients receiving preoperative CRT, a randomized study designed specifically to assess the non-inferiority of the conservative approach using local recurrence and OS as the primary endpoints, as well as innovative methods for accurately evaluating post-CRT remnant disease before surgery, are required. Meanwhile, local excision after preoperative CRT is likely to remain a second-choice therapeutic option for LARC patients who are elderly and frail and who are unfit to undergo conventional radical surgery.

NEW RT METHODS

The preoperative RT scheme (long-course) for LARC usually uses three-dimensional conformal techniques delivering 45 Gy to the tumor and pelvic lymphatics, followed by additional irradiation to the gross tumor to a total dose of 50.4 Gy in 28 fractions over 5.5 weeks. Concurrently, 5-fluorouracil-based chemotherapy is administered, followed by surgery at 4 to 8 weeks after the completion of CRT. Although various drugs (capecitabine, irinotecan, and oxaliplatin) and molecular targeted therapies (epidermal growth factor receptor inhibitors, vascular endothelial growth factor inhibitors) are being explored as single agents or in combination [46–48], the RT scheme has long been uniformly standardized. Nonetheless, some studies concerning innovative RT methods have been done to enhance the efficacy or to decrease the toxicity. Kim et al. [49] treated 38 LARC patients preoperatively with pelvic RT of 43.2 Gy/24 fractions, and a boost treatment with 7.2 Gy/12 fractions was administered concomitantly during the latter half of pelvic RT. This modified RT fractionation was designed to shorten the treatment period and, thus, escalate the effective dose. However, this concomitant boost irradiation did not improve the clinical outcome compared with conventional preoperative regimens. In other studies, the intensity-modulated RT technique was investigated in preoperative CRT for LARC patients and demonstrated effective reductions in the irradiated small bowel volume and the bowel toxicity [50, 51]. Compared with conventional RT techniques, intensity-modulated RT shows better coverage of the planning target volume and better sparing of organs at risk, and has been rapidly implemented for various tumor types [52]. Much remains to be explored in preoperative RT strategy for rectal cancer regarding dose fractionation (short-course vs. long-course), treatment planning and delivery techniques, interaction with drugs, and molecular modulators of radiation resistance.

CONCLUSION

Preoperative RT has played a pivotal role in multimodality management for LARC patients. It provides significant benefit in local disease control even with optimal surgical techniques.

Additionally, it permits early recognition of specific tumor biology for each patient. Based on pathologic CRT response identified through surgical pathology, prognosis can be predicted; thus, subsequent postoperative treatment may be tailored. Furthermore, when this pathologic CRT response can be accurately determined before surgery, or even before initiation of CRT, risk-adjusted treatments, such as CRT intensification or conservative surgery, can be recommended for selected patients (Fig. 1). Research on risk-adapted strategies for treating LARC patients should be continued to improve tumor control and simultaneously to lower treatment toxicity.
CONFLICT OF INTEREST

No potential conflict of interest relevant to this article was reported.
