Short term and intermediate term comparison of endarterectomy versus stenting for carotid artery stenosis: systematic review and meta-analysis of randomised controlled clinical trials

Pascal Meier, clinical and research fellow,1,2 Guido Knapp, senior scientist,3 Umesh Tamhane, research fellow,1 Seemant Chaturvedi, professor of neurology,4 Hitinder S Gurm, assistant professor of cardiology1,2

ABSTRACT

Objective To evaluate the relative short term safety and intermediate term efficacy of carotid endarterectomy versus carotid artery stenting.

Design Systematic review and meta-analysis.

Data sources BIOSIS, Embase, Medline, the Cochrane central register of controlled trials, International Pharmaceutical Abstracts database, ISI Web of Science, and Google scholar and bibliographies, from 1 January 1990 to 25 July 2009.

Study selection Randomised controlled trials comparing carotid endarterectomy with carotid artery stenting in patients with carotid artery stenosis with or without symptoms.

Data extraction Primary end point was a composite of mortality or stroke. Secondary end points were death, stroke, myocardial infarction, or facial neuropathy (as individual end points), and mortality or disabling stroke (as a composite end point).

Data synthesis 11 trials were included (4796 patients); 10 reported on short term outcomes (n=4709) and nine on intermediate term outcomes (1-4 years). The periprocedural risk of mortality or stroke was lower for carotid endarterectomy (odds ratio 0.67, 95% confidence interval 0.47 to 0.95; P=0.025) than for carotid stenting, mainly because of a decreased risk of stroke (0.65, 0.43 to 1.00; P=0.049), whereas the risk of death (1.14, 0.56 to 2.31; P=0.727) and the composite end point mortality or disabling stroke (0.74, 0.53 to 1.05; P=0.088) did not differ significantly. The odds of periprocedural myocardial infarction (2.69, 1.06 to 6.79; P=0.036) or cranial nerve injury (10.2, 4.0 to 26.1; P<0.001) was higher in the carotid endarterectomy group than in the carotid stenting group. In the intermediate term, the two treatments did not differ significantly for stroke or death (hazard ratio 0.90, 95% confidence interval 0.74 to 1.1; P=0.314).

Conclusions Carotid endarterectomy was found to be superior to carotid artery stenting for short term outcomes but the difference was not significant for intermediate term outcomes; this difference was mainly driven by non-disabling stroke. Significantly fewer cranial nerve injuries and myocardial infarctions occurred with carotid artery stenting.

INTRODUCTION

Carotid stenosis is responsible for around 20% of strokes in the adult population.1 Treatment of carotid stenosis therefore lies in decreasing the risk of stroke or stroke related deaths.2 The main treatment is currently carotid endarterectomy, a procedure that has shown to be superior to medical therapy in the prevention of stroke and death in patients with carotid stenosis with and without symptoms.3 Carotid angioplasty or carotid artery stenting has been emerging as a newer and less invasive alternative. Initial studies indicate that this approach is feasible, safe, and effective. However, the results of randomised controlled trials comparing carotid artery stenting with carotid endarterectomy are ambiguous.4,5 A recent meta-analysis of randomised controlled trials reported an increased risk of stroke or death within 30 days of carotid artery stenting compared with carotid endarterectomy.6 In addition, a larger observational study7 and a multicentre randomised controlled trial8 found a higher periprocedural (<30 days) incidence of stroke with carotid artery stenting compared with carotid endarterectomy. In this observational study, treatment allocation was not random and therefore the study is prone to confounding;8 patients at high surgical risk underwent carotid artery stenting and had inherently higher risks of myocardial infarction and death.

We evaluated the short term (periprocedural) safety and intermediate term efficacy of carotid artery stenting versus carotid endarterectomy for stroke or death in patients with carotid stenosis with or without symptoms.

METHODS

The study was done according to the preferred reporting items for systematic reviews and meta-analyses (PRISMA) guidelines.10 Two authors (HSG and PM) planned and designed the study and created an electronic database with variables of interest (Microsoft
American College of Cardiology, the European Society of Cardiology, the 2006-8 proceedings of the Transcatheter Cardiovascular Therapeutics, and the American Heart Association. We also considered published review articles, editorials, and internet based sources of information (www.tctmd.com, www.theheart.org). Medical subject headings and keyword searches included the terms carotid endarterectomy, carotid artery stenting, stroke, myocardial infarction, and death. We reviewed the reference lists of selected articles for other potentially relevant citations. Authors of selected studies were contacted for further information if necessary, such as the hazard ratios for intermediate term data.

Study selection
Two investigators (HSG and PM) identified potential studies and assessed them for eligibility using a two step process. Firstly, they independently reviewed the titles and abstracts of all citations to identify potentially relevant studies and to exclude duplicates. Secondly, they reviewed the corresponding publications in full text to assess if studies met the inclusion criteria—that is, randomised controlled trials that directly compared carotid endarterectomy with carotid artery stenting; had stroke or death, or both as end points; and had at least 30 days of follow-up. Reviewers were not blinded to study authors or outcomes. The final inclusion of studies was based on agreement between the reviewers.

Data extraction and quality assessment
Three investigators (PM, UT, and HSG) used the standardised extraction database (Microsoft Excel) to extract information on outcome (numbers of patients, event rates for periprocedural and intermediate term death and stroke, both as single end points and as a composite end point) with hazard ratios; periprocedural death or disabling stroke (composite end point); myocardial infarction; and facial neuropathy as well as

---

**Characteristics of studies included in meta-analysis**

| Study (years) | Short term/intermediate term data | Interventions (No of patients) | Duration of follow-up | Proportion of patients (%) | Mean age (years) |
|--------------|----------------------------------|-------------------------------|-----------------------|---------------------------|-----------------|
| Naylor et al29 (1998) | Yes/no | Carotid endarterectomy (n=12) v carotid artery stenting (n=11) | 30 days | 0% 100% 0% | 66.7 v NA |

NA=not available. CAVATAS=Carotid and Vertebral Artery Transluminal Angioplasty Study; SAPPHIRE=Stenting and Angioplasty with Protection in Patients at High Risk for Endarterectomy; EVA-3S=Endarterectomy Versus Angioplasty in patients with Symptomatic Severe carotid Stenosis; SPACE=Stent-Supported Percutaneous Angioplasty of the Carotid Artery versus Endarterectomy; BACASS=Baselet Carotid Artery Stenting Study; ICSS=International Carotid Stenting Study.
The weighted average incidence of periprocedural death or stroke was 5.4% (95% confidence interval 4.0% to 7.0%) for carotid endarterectomy and 7.3% (4.9% to 10.1%) for carotid artery stenting. The risk was significantly lower for carotid endarterectomy compared with carotid artery stenting (odds ratio 0.67, 95% confidence interval 0.47 to 0.95; P = 0.025; I² = 37.4%; P = 0.119) (fig 2). The studies defined periprocedural stroke differently. The Carotid and Vertebro-Artery Transluminal Angioplasty Study (CAVATAS) only counted a stroke event if symptoms lasted longer than seven days. Neither funnel plot, Egger’s plot (see web extra fig 1), nor formal tests (Egger’s and arc sine test) indicated potential publication bias or small study bias (P = 0.932 and P = 0.989, respectively). Further analyses to evaluate heterogeneity of study results showed an important change in the comparability of the two procedures over time. The distinct inferiority of carotid artery stenting compared with carotid endarterectomy shown early on by cumulative meta-analysis diminished over time when newer trials were added sequentially (see web extra fig 2). Another factor was the high number of trials for differential follow-up intervals and patients who were lost to follow-up. All analyses were done on an intention to treat basis. When an event did not occur in one group we used continuity correction. We evaluated the presence of heterogeneity across trials with the Q and Higgins’s and Thompson’s I² statistics. I² can be interpreted as the percentage of variability due to heterogeneity between studies rather than to sampling error. To assess the effect of individual studies on the summary estimate of effect, we carried out an influence analysis, in which we recalculated the pooled estimates by omitting one study at a time. We assessed publication bias visually (funnel plot) and by formal tests (Egger’s test of intercept and the arc sine test). Average weighted incidence of events is presented for both treatments; calculation was based on a random effect analysis using the inverse variance method and a Freeman-Tukey double arc sine transformation. All data are presented with 95% confidence intervals. Two investigators (GK and PM) carried out analyses independently using R, version 2.9.0, package meta and metaphor, and SAS version 9.1 (Proc nlmixed). RESEARCH

RESULTS

Of 58 full text articles reviewed, 11 trials met the inclusion criteria (fig 1). Ten reported on short term outcomes and nine on intermediate term outcomes; among those, one reported exclusively on intermediate term outcomes. The Carotid Revascularization using Endarterectomy or Stenting Systems (CARESS) trial was not included in this analysis as treatment assignment was not randomised. The table summarises the characteristics of the 11 trials.

Periprocedural outcome

To estimate the pooled odds ratio for carotid endarterectomy compared with carotid artery stenting we combined the data on short term binary outcomes from the selected studies using a random effects model with inverse variance weights. When the estimate of the heterogeneity variable is zero, the random effect model coincides with a fixed effect meta-analysis. Because several P values were around the predefined significance threshold of 0.05, we carried out sensitivity analyses using alternative analytical models for these variables. The odds ratios were recalculated using three approaches: on the basis of the Hartung-Knapp variance estimates (R package “metafor”), which are usually more conservative but have better coverage probabilities; an “exact” likelihood approach (binomial-normal hierarchical model; SAS, Proc nlmixed); and the Peto method.

To further evaluate trends over time we used a cumulative meta-analytical model (random effects). This analysis cumulates the effects stepwise over time by integrating newly published studies sequentially according to the date of publication. To account for varying time to event for intermediate term follow-up, we used hazard ratios of time to events (R package “meta,” function metagen). This approach accounts...
artery stenting (odds ratio 1.14, 95% confidence interval 0.56 to 2.31; P=0.727; F=0%; P=0.697) (fig 3).

Data on the composite end point of periprocedural disabling stroke or death was available from eight trials; no event was observed in two. 

The weighted average event rate was 2.9% (95% confidence interval 1.9% to 4.3%) for carotid endarterectomy versus 3.8% (2.3% to 5.7%) for carotid artery stenting. In the direct comparison, this difference was not significant (odds ratio 0.74, 95% confidence interval 0.53 to 1.05; P=0.088; F=0%; P=0.600). For the Stent-Supported Percutaneous Angioplasty of the Carotid Artery Versus Endarterectomy (SPACE) trial, the composite end point was defined as ipsilateral disabling stroke or death; for the International Carotid Stenting Study (ICSS), only per protocol data were available for this end point and these data were used instead of intention to treat data.

The rate of periprocedural myocardial infarction was reported in four trials. 

The average weighted event rate was 7.5% (95% confidence interval 5.8% to 9.4%) for carotid endarterectomy versus 0.45% (0.01% to 1.0%) for carotid artery stenting. Overall, the risk was higher in the carotid endarterectomy group (odds ratio 16.29, 95% confidence interval 1.06 to 6.79; P=0.036; F=0%; P=0.700) (fig 4).

Six studies reported on periprocedural cranial facial neuropathy; no event occurred in one study. 

The average weighted event rate was 7.5% (95% confidence interval 5.8% to 9.4%) for carotid endarterectomy versus 0.45% (0.01% to 1.0%) for carotid artery stenting. Overall, the risk was higher in the carotid endarterectomy group (odds ratio 16.29, 95% confidence interval 1.06 to 6.79; P=0.036; F=0%; P=0.700) (fig 4).

Secondary end points

Periprocedural stroke was reported in nine studies, two of which did not observe any stroke during this period. The average weighted incidence of stroke was 4.2% (95% confidence interval 2.7% to 6.1%) for carotid endarterectomy versus 5.7% (3.0% to 9.2%) for carotid artery stenting. The risk of stroke was significantly lower for carotid endarterectomy (odds ratio 0.65, 95% confidence interval 0.43 to 1.00; P=0.049; I²=48.4%; P=0.071) (fig 3).

Periprocedural mortality was reported as an end point in eight trials; in three, no death was observed in either group. The average weighted incidence of death was 1.4% (95% confidence interval 0.08% to 2.1%) for carotid endarterectomy and 1.2% (0.7% to 1.8%) for carotid artery stenting. Overall, there was no significant difference between patients treated with carotid endarterectomy versus carotid artery stenting (odds ratio 0.63, 95% confidence interval 0.42 to 0.94; P=0.025; I²=47.2%; P=0.056).

We also carried out an analysis including trials that only enrolled patients with carotid stenosis who had symptoms while excluding the SAPPHIRE (Stenting and Angioplasty with Protection in Patients at High
Risk for Endarterectomy) trial\(^{22,23}\) and Brooks et al’s\(^{30}\) trial that predominantly or exclusively consisted of asymptomatic patients. For the primary end point the odds ratio for carotid endarterectomy versus carotid artery stenting was similar (0.63, 0.44 to 0.92; \(P=0.017\)).

Intermediate term outcomes

The risk for the intermediate term composite end point stroke or death did not differ significantly between carotid endarterectomy and carotid artery stenting. Among the nine trials reporting on long term results, hazard ratios were available for the four larger trials; data for the SAPHIRE trial\(^{22,23}\) were provided by the study investigators. For the data of the CAVATAS trial,\(^{25}\) the hazard ratios were controlled for sex, age, and trial centre, whereas the other studies provided unadjusted hazard ratios; furthermore, the hazard ratios of the CAVATAS trial were based on deaths and disabling strokes. Data on the ICSS trial\(^{26}\) were not considered because the maximum follow-up time was limited to 120 days. No difference was found between carotid artery stenting and carotid endarterectomy (hazard ratio 1.11, 95% confidence interval 0.91 to 1.35; \(P=0.315\); \(F=0\%\); \(P=0.400\)) (fig 6).

We also analysed event data based on the classic incidence of events (as for short term data). Binary data (events and total number of patients per group) were available for nine trials and did not show any difference in outcome (odds ratio 0.87, 95% confidence interval 0.71 to 1.07; \(P=0.190\); \(F=0\%\); \(P=0.432\)) (fig 7).

The risk of stroke in the intermediate term was not significantly different between the two treatments in the four studies providing information on time to event analyses (hazard ratio 0.86, 95% confidence interval 0.67 to 1.10; \(P=0.216\); \(F=4.3\%\); \(P=0.371\)). The classic analysis based on eight trials providing binary data on this end point\(^{25,27,28,30,32,33}\) gave an odds ratio of 0.78 (95% confidence interval 0.56 to 1.09); \(P=0.151\) (\(F=12.3\%\); \(P=0.337\)). Intermediate term mortality did not differ significantly for carotid endarterectomy compared with carotid artery stenting for the trials (hazard ratio 1.09, 0.76 to1.57; \(P=0.625\); \(F=6.3\%\); \(P=0.306\)), but time to event based data were available for only two trials. The classic analysis based on seven trials providing binary data on this end point\(^{25,27,28,30,32,33}\) gave an odds ratio of 1.04 (95% confidence interval 0.78 to 1.38); \(P=0.779\) (\(F=0\%\); \(P=0.856\)).

DISCUSSION

This meta-analysis indicates that carotid endarterectomy is associated with better periprocedural outcomes than carotid artery stenting. This disparity was primarily driven by a difference in risk of procedural non-disabling stroke, which seemed to be higher in patients treated with carotid artery stenting. Conversely, the risk of facial neuropathy and periprocedural myocardial infarction was higher with carotid endarterectomy. In the intermediate term to long term, primary or secondary end points did not differ significantly, suggesting similar efficacy of the two procedures.

Since carotid revascularisation is carried out solely for the prevention of future events, the rate of procedural complications (especially stroke) is a key driver of the risk-benefit ratio. The trade-off between the procedural risk and the longer term benefit has to be evaluated carefully; this also has to be kept in mind when interpreting trials comparing procedures for treating carotid artery stenosis; especially since none of the trials included a best medical therapy only group.

Carotid endarterectomy has been shown to reduce the overall risk for stroke and death compared with medical treatment in patients with relevant carotid artery stenosis both with symptoms\(^{34}\) and without symptoms\(^{35}\). Based on these trials, an acceptable upper limit of perioperative rate for stroke or death has been determined to be around 3% for asymptomatic patients\(^{35}\) and 6% for patients with symptoms.\(^{36,37}\) Congruent with this, our analysis of mainly patients with symptoms showed a procedure related event rate of 5.4% for carotid endarterectomy. For carotid artery stenting, the average perioperative event rate was 7.3% in our analysis. In this perspective, evaluation of expected excess benefit for an individual patient is difficult and has to be based on his or her estimated baseline risk of stroke without treatment and on life expectancy. Moreover, the efficiency of medical treatment has probably improved, since most of the pivotal trials on carotid endarterectomy did not prescribe to the aggressive risk factor reduction that would be considered standard today for patients with established atherosclerosis.\(^{38,39}\)

Failure to account for trends in outcomes over time is a major limitation of a meta-analysis evaluating an emerging technology. This is evident in the specialty of cardiovascular medicine as the outcomes with carotid artery stenting have continued to improve and the results reported in recent registries have been superior to those in most of the trials included in the meta-analysis. Whereas the average 30 day rate for stroke or death was 7.3% in the included trials, the Emboshield and Xact Post Approval Carotid Stent Trial (EX) registry (which included 2145 high risk surgical patients) and the Carotid ACCULINK/ACCUNET Post
Approval Trial to Uncover Rare Events (C2) (which included 4175 patients) showed 30 day rates for stroke or death of only 4.1% and 3.4%, respectively.40 This may be attributed to a learning curve in the emerging technique of carotid artery stenting with improvement in equipment design, optimisation of patient selection, adequate training of operators, and better attention to pharmacotherapy (see web extra fig 2). This learning curve has been a major drawback for some of the largest trials in carotid artery stenting where a significant proportion of operators had limited experience, 39% of patients in the Endarterectomy Versus Angioplasty in patients with Symptomatic Severe carotid Stenosis (EVA-3S) trial were treated by doctors with modest experience of the procedure41 and use of emboli protection devices and dual antiplatelet therapy was not universal.23 32 This would suggest that carotid artery stenting as carried out in most patients included in the meta-analysis would be expected to be inferior to carotid endarterectomy, whereas the intermediate term outcome would be similar. These findings have important implications for patients undergoing carotid revascularisation. Currently, use of carotid artery stenting in the United States is restricted by Centers for Medicare and Medicaid Services guidelines to patients at high risk for carotid endarterectomy or those enrolled in clinical trials. The results of this meta-analysis suggest that it may be premature to consider any revision to these guidelines. Furthermore, the consistently inferior short term results of carotid artery stenting as done in these studies suggests a need for a strategy aimed at minimising the risk of procedural stroke. This would involve adequate case selection, rigorous training and credentialing of operators, appropriate strategies to reduce procedural embolic phenomenon, and suitable drugs. Current trials must ensure that such mechanisms are in place and that patients are clearly informed of the risks in undergoing carotid artery stenting versus carotid endarterectomy. It is worth noting that factors rendering patients at high risk from carotid endarterectomy are not necessarily identical to those for carotid artery stenting. Although comorbidities are the major risk factors with carotid endarterectomy, carotid artery stenting outcomes are mainly influenced by the anatomy of local vessels, and both factors have to be considered in treatment decision making.32

Although there have been multiple recent meta-analysis in carotid revascularisation,44 45 our study significantly extends the work because of a larger population, a more robust methodology, and longer term follow-up data. Earlier studies have erroneously split composite end points from the SAPPHIRE trial,22 33 which we confirmed from study authors. Also, previous meta-analysis preferentially reported on a fixed effect model instead of the more conservative random effect model, which is more appropriate here owing to considerable study heterogeneity.6 Furthermore, we used appropriate transformations to generate weighted proportions for procedural complication rates.

Finally, we used time to event analysis for longer term outcomes, and the pooled hazard ratio provides a more accurate assessment of events compared with odds ratios or risk ratios that ignore possible variation in time to events and incomplete follow-up. This is particularly relevant to events such as stroke or death where an event early in the study would be considerably more devastating than one occurring later.

Heterogeneity of study results
Even though heterogeneity of study results was moderate, relevant aspects of dissimilarities in study designs have to be considered. Most of the studies excluded asymptomatic patients whereas one study evaluated asymptomatic patients exclusively30 and in another trial two thirds of patients were asymptomatic.22 Moreover, average surgical risk of the study populations were different; the SAPPHIRE trial22 included high risk patients exclusively. This trial, in contrast with most others, found a superiority of carotid artery stenting over carotid endarterectomy. This suggests that since intermediate term outcomes are similar it might be appropriate to select a revascularisation strategy based on the procedural risk of patients. However, exclusion of these two studies including predominantly asymptomatic patients did not change the overall outcome of our analysis.

A major reason for heterogeneity between the studies was because almost half of the trials were stopped prematurely, before the prespecified sample size was reached. Early stopping can lead to overestimation of treatment effects (stop at random high) as shown in several previous analyses.44 45 For two of the early stopped trials, however, the decision was not based on differential outcomes but on problems with funding22 or recruitment,22 whereas for three trials the early stopping was based on large differences in risk for the compared treatments.21 26 29 These three trials may have led to some overestimation of the superiority of carotid endarterectomy. This fact highlights the importance of completion of currently ongoing trials—for example, CREST (Carotid Revascularization
Fig 7 Forest plot of odds ratios of intermediate term risk for composite of stroke or death

Endarterectomy versus Stent Trial and ACT 1 (Asymptomatic Carotid Stenosis, Stenting versus Endarterectomy Trial) — to define the best contemporary carotid revascularisation strategy.

Furthermore, concomitant drug treatment differed among the included trials. Earlier trials required aspirin treatment only with no pretreatment, whereas the Wallstent trial used ticlopidine for four weeks after the procedure, and more recent studies used clopidogrel for about 2-4 weeks after the procedure, often for 72 to 24 hours before the stenting procedure. This may be particularly relevant to the periprocedural outcomes for carotid stenting where inadequate platelet inhibition may predispose to early thrombosis and embolisation with the attendant hazard of stroke.

Limitations of the meta-analysis

Most of the patients in this meta-analysis had symptoms; asymptomatic patients were under-represented and a generalisation to this population would be speculative. Asymptomatic patients generally have a lower procedural risk, but specific evidence for this group is currently limited to one trial that did not observe an event in either group. Conceptually, preventive treatment of carotid artery disease rather than intervening after a first cerebrovascular event would seem meaningful, although a similar degree of prevention may be achieved by aggressive medical therapy. More data on this population is required, although contemporary registry studies suggest a persistently high risk of stroke in asymptomatic patients with carotid stenosis.

Two of the included studies have only been presented at scientific meetings or published as abstracts and did not undergo a rigorous peer review process. The quality assessment of these studies is therefore limited. Exclusion of these trials from the analysis did not change the results. Finally, there are several limitations of the included studies, which may have introduced a systematic bias against carotid stenting and potentially led to an overestimation of the benefit of carotid endarterectomy. Firstly, the primary end point of most studies was a composite of death or stroke. This end point has been used traditionally for most trials in the discipline of carotid endarterectomy. This composite end point seems meaningful as an efficacy end point but neglects important safety issues such as periprocedural myocardial infarction and cranial neuropathy. The incidence of each of these events was less than 1% on average for carotid stenting in the included trials whereas for carotid endarterectomy the average incidence for myocardial infarction was 2.6% and that for cranial neuropathy was 7.5%. Even though most of the cranial nerve neuropathies are transient, about 4% persist over several months and about 0.5% are permanent. Such injuries to the cranial nerve and also myocardial infarctions can have an effect on a patient’s quality of life similar to that after a stroke. Future trials should consider the use of composite end points that also include relevant safety end points. Secondly, most included studies based their preprocedural assessment mainly on carotid duplex sonography, which generally gives an insufficient assessment of the vessel anatomy. Vascular anatomy is a key determinant of periprocedural risk for carotid artery stenting. However, the periprocedural risk with carotid endarterectomy is mainly defined by clinical risk factors that are usually available at first encounter with patients and may have served to exclude high risk patients from inclusion in a study. This could potentially introduce a selection bias that disfavours carotid stenting. Finally, most trials required extensive experience of the surgeons carrying out carotid endarterectomy, whereas the corresponding requirements for interventionists doing carotid stenting were less stringent. The EVA-3S trials, for example, required surgeons to have carried out at least 25 procedures in the previous year, whereas interventionists had to have carried out at least 12 carotid stenting procedures overall or only five if they had done 35 stenings of the supra-aortic trunk; those who had less experience could enrol patients with a tutor, who was required to have carried out at least 12 procedures overall. Thus

| Study                  | No of patients/No of events | Carotid endarterectomy | Carotid artery stenting | Odds ratio (95% CI) | Odds ratio (95% CI) |
|------------------------|----------------------------|------------------------|-------------------------|---------------------|---------------------|
| CAVATAS 2001          | 253/36                     | 251/36                 | 0.99 (0.60 to 1.63)     |                     |
| Wallstent 2001        | 112/4                      | 107/13                 | 0.27 (0.08 to 0.85)     |                     |
| Brooks et al 2001     | 51/1                       | 53/0                   | 3.18 (0.13 to 79.83)    |                     |

Fig 6 Forest plot of hazard ratio of intermediate term risk for composite of stroke or death
Significantly fewer cranial nerve injuries and myocardial infarctions occurred with carotid stenting compared with carotid endarterectomy.

The lack of similar operator experience may have biased the results against carotid stenting.

Conclusion

In our meta-analysis including 4796 patients with carotid stenosis predominantly with symptoms, carotid endarterectomy was associated with a lower risk for the primary end point of death or stroke. This difference was mainly driven by the lower incidence of peri-procedural non-disabling or minor strokes. A relevant temporal impact exists indicating a continuously improving outcome for the newer carotid artery stenting approach compared with the longer established carotid endarterectomy. We found no significant differences in numbers of major or disabling strokes or deaths, whereas significantly fewer cranial nerve injuries and myocardial infarctions occurred with carotid artery stenting. Intermediate term outcomes were not significantly different between the two interventions. Patients with symptoms requiring carotid revascularisation should currently be offered carotid endarterectomy as first choice, with carotid artery stenting reserved for patients at high surgical risk. Trials of contemporary carotid artery stenting versus carotid endarterectomy are needed to better understand the role for each treatment in patients with or without symptoms.

We thank Whitney Townsend (librarian, Taubman Medical Library, University of Michigan) for her inputs and help during the literature search and Don Cafili (Beth Israel Hospital, Harvard Medical School) for providing data on the SAPPHIRE trial.

Contributors: HSG and PM conceived and designed the study. HSG, PM, SC, GK, and UT revised the paper critically for important intellectual content. All authors had full access to the data (including statistical analysis, and interpretation of the data) or the preparation, review, or approval of the manuscript.

Competing interests: SC is a consultant for Abbott Vascular. Ethical approval: Not required.

Data sharing: Datasets and statistical code for R and SAS are available from the corresponding author at hgurom@umich.edu.
