Rapid social connectivity

Itai Benjamini†
Jonathan Hermon‡

Abstract

Given a graph $G = (V, E)$, consider Poisson($|V|$) walkers performing independent lazy simple random walks on $G$ simultaneously, where the initial position of each walker is chosen independently with probability proportional to the degrees. When two walkers visit the same vertex at the same time they are declared to be acquainted. The social connectivity time $SC(G)$ is defined as the first time in which there is a path of acquaintances between every pair of walkers. It is shown that when the average degree of $G$ is $d$, with high probability

$$c \log |V| \leq SC(G) \leq Cd^{1+5} \log^3 |V|,$$

when $G$ is regular the lower bound is improved to $SC(G) \geq \log |V| - 6 \log \log |V|$, with high probability. We determine $SC(G)$ up to a constant factor in the cases that $G$ is an expander and when it is the $n$-cycle.

Keywords: social network; random walks; giant component; coalescence process.

1 Introduction

Consider the following model for a social network which we call the random walks social network model or for short, the social network model. We write SN as a shorthand for social network. Let $G = (V, E)$ be a finite connected graph, which is the underlying graph of the SN model. In the model there are walkers performing independent lazy simple random walks (LSRW) on $G$, defined as follows. If a walker’s current position is $v$, then the walker either stays put w.p. $1/2$, or moves to one of the neighbors of $v$ w.p. $1/2d_v$, where $d_v$ is the degree of $v$. The walkers perform their LSRWs
Rapid social connectivity

simultaneously (i.e. at each time unit they all perform one step, which may be a lazy step).

At time 0 the number of walkers at vertex \( v \) is set to be \( N_v \), where \((N_v)_{v \in V}\) are independent random variables, where for each vertex \( v \), we have that \( N_v \sim \text{Poisson}(\bar{\pi}_v) \), where \( \bar{\pi} := |V|/\pi \) and \( \pi_v := d_v/(2|E|) \) is the stationary distribution of the random walk on \( G \).

A directed graph \( G \) is called Eulerian if for every vertex \( v \) the indegree of \( v \) equals its outdegree, denoted (unambiguously) by \( d_v \). One can define LSRW on \( G = (V,E) \) in an analogous manner to the undirected case (e.g., [6]). Its stationary distribution is \( \pi_v := d_v/|E| \) (here \( E \) is the set of directed edges). We say that a directed graph \( G = (V,E) \) is connected if for all \( u,v \in V \) there is a directed path in \( G \) from \( u \) to \( v \).

We shall prove our main results in the setup that \( G \) is a connected Eulerian digraph. Note that any graph can be thought of as an Eulerian digraph in which each edge appears with both orientations.

However, the examples we consider shall all be graphs. Namely, the \( n \)-cycle and regular expanders.

We say that two walkers \( w, w' \) have met by time \( t \), which we denote by \( w \overset{t}{\leftrightarrow} w' \), if there exists \( t_0 \leq t \) such that they have the same position at time \( t_0 \). After two walkers meet they continue their walks independently without coalescing. “Meeting by time \( t \)” is a symmetric relation. It induces the equivalence relation of having a path of acquaintances by time \( t \), denoted by \( \overset{t}{\sim} \), defined as follows. Two walkers \( a \) and \( b \) have a path of acquaintances by time \( t \) iff there exist \( k \in \mathbb{N} \) and walkers \( a = c_0, c_1, \ldots, c_k, c_{k+1} = b \) such that \( c_i \overset{t}{\leftrightarrow} c_{i+1} \), for all \( 0 \leq i \leq k \). Note that we are not requiring the sequence of times in which the walkers met to be non-decreasing, which is the main difference between the SN model and some existing models for spread of rumor/infection (e.g. the \( A + B \to 2B \) model [14] and the Frog model [18, 3, 4, 17, 12], see §2.6 for a description of these models and a discussion about their relationship to the SN model). Consequently, the SN model often evolves faster than such models. However, Conjecture 2.3 suggests one sense in which these models might also evolve rapidly.

We are interested in the coalescence process of the equivalence classes of \( \overset{t}{\sim} \) (as \( t \) varies). In particular, we are interested in the social connectivity time \( \text{SC}(G) \), defined as the minimal time in which there is only one class (i.e. every pair of walkers have a path of acquaintances between them).

2 Our results

2.1 General graphs

Our main result is

**Theorem 1.** Let \( G = (V,E) \) be a connected \( n \)-vertex Eulerian digraph of average degree \( d = |E|/n \). Denote \( r_* := \min_{v \in V} d_v/n \). Then there exist absolute constants\(^1\) \( C, M, c > 0 \) such that

\[
P \left[ \text{SC}(G) > C d^{1+5\xi} (\log n)^3 \right] \leq M/n,
\]

where \( \xi := 1_G \text{ is not regular}. \)

\[\forall \alpha \in (0, 1), \exists c_\alpha > 0, \quad P[\text{SC}(G) \leq \alpha \log n] \leq 3 e^{-c_\alpha^2 n^\alpha}. \tag{2.2}\]

\(^1\)This is sometimes referred to as being strongly connected.

\(^2\)We use \( C, C', C_0, C_1, K, M, \ldots \) (resp. \( \delta, \varepsilon, c, c', c_0, c_1, \ldots \)) to denote positive absolute constants which are sufficiently large (resp. small) to ensure that a certain inequality holds. Similarly, we use \( C_0 \) (resp. \( c_0 \)) to refer to sufficiently large (resp. small) positive constants, whose value depends on the parameters appearing in subscript. Different appearances of the same constant at different places may refer to different numeric values.
Rapid social connectivity

Note that (2.2) is meaningful as long as \( r_* \geq |V|^{\beta - 0.5} \) for some \( \beta > 0 \). Theorem 5.5 gives an extension covering in particular the case \( r_* \geq |V|^{\beta - 1} \) for some \( \beta > 0 \). When \( G \) is a regular graph we have the following improved lower bounds on \( SC(G) \).

**Theorem 2.** There exist \( c, C > 0 \) so that for every finite connected regular graph \( G = (V, E) \),

\[
P[SC(G) < \log |V| - 6 \log \log |V|] \leq C/ \log |V|. \tag{2.3}
\]

\[
P[SC(G) < s_*(G)] \leq C \exp \left( -c \sqrt{|V| (\log |V|)^{-4}} \right), \tag{2.4}
\]

where \( P \) is the transition matrix of the LSRW,

\[
\kappa_t := \min_{v \in V} \sum_{i=0}^{t} P^{2i}(v, v) \quad \text{and} \quad s_*(G) := \min \left\{ t : \frac{t+1}{\kappa_t+1} > \frac{1}{32} \log |V| \right\}.
\]

Note that \( s_*(G) > \frac{1}{32} \log |V| \). We include (2.3), despite this, as it is sharp, up to the value of the sub-leading term, and the failure probability, see the discussion below about extremality of the complete graph. In some cases \( s_*(G) \geq C(|V|)^2 \). For instance, for the \( n \)-cycle \( C_n \) we have that \( P^{2i}(v, v) = \Theta(\frac{1}{\sqrt{n}}) \) and so \( s_*(C_n) = \Theta((\log n)^2) \). Hence by (2.4) \( P[SC(C_n) < c (\log n)^2] = o(1) \). This is not surprising as initially there will be intervals of length \( \Omega(\log n) \) which will not be occupied by a single particle. This is why in terms of the lower bound on \( SC(C_n) \) it is more interesting to study the case that initially there is one walker per site (as done in Theorem 3). Conversely, there exists some \( C > 0 \) such that the probability that \( SC(C_n) > Cs_*(C_n) \) is at most \( C^2/n \) (see §2.3). We conjecture that there exists some universal constant \( C > 0 \) such that for every connected finite vertex transitive graph \( G \) (Definition 8.1) \( \frac{1}{C} \leq E[SC(G)]^{1/2} \leq C \).

### 2.2 Some remarks concerning our main results

**Degree dependence:** We now discuss the degree dependence in (2.1) and also a refinement of (2.1). Example 8.6 (resp. 8.7) describes for some absolute constants \( c_0, c_1, C_0 > 0 \) for all sufficiently large \( n \) and all \( C_0 \leq d_n \leq c_0 n \) a family of graphs \( G_n = (V_n, E_n) \) such that \( n \leq |V_n| \leq C_0 n \) which are \( d_n \)-regular (resp. of average degree \( d_n \)) for which \( P[SC(G_n)] \geq c_1 d_n^2 \log^2(|V_n|/d_n) \) for every \( d_n \geq c_1 \) (resp. \( P[SC(G_n)] \geq c_1 d_n^2 \log^2(|V_n|/d_n) \geq c_1 \)). This shows that the linear dependence on \( d \) in (2.1) is optimal for regular \( G \) and that we can have \( E[SC(G)] \geq n \) for an \( n \)-vertex regular \( G \) and \( E[SC(G)] \geq n^2 \) for non-regular \( G \).

If \( G \) is \( d \)-regular and in addition for every set \( A \subset V \) such that \( |A| \leq \frac{2}{3}(|V| + |V|^{2/3}) \), we have that

\[
|\{(u, v) \in E : u \in A, v \notin A \text{ or } u \notin A, v \in A\}| \geq c_0 d,
\]

then the degree dependence in (2.1) can be eliminated and (2.1) can be improved to

\[
P[SC(G) > C_0^{-2} \log^3 |V|] \leq M/|V|,
\]

for some absolute constants \( C, M \) (see Proposition 4.12, part (iii)).

Now consider the case that \( G \) is a connected \( n \)-vertex Eulerian digraph of average degree \( d \). Let \( \xi := 1_G \) be not regular. From the proof of Theorem 1 it follows that we can replace \( C_{d,d^0+5\xi} (\log n)^2 \) in (2.1) by \( C^* t_*(G) d_{1+3\xi} \log n \), for some \( t_*(G) \leq C d_{2\xi} (\log n)^2 \). Namely,

\[
t_*(G) := \inf \{ t : \max_{x,y} |P^t(x, y) - \pi_y| \leq d_y/(3 \cdot 2^0 d \log n) \},
\]

\footnote{We write \( o(1) \) for terms which vanish as \( n \to \infty \) (or some other index, which is clear from context). We write \( f_n = o(g_n) \) or \( f_n \ll g_n \) if \( f_n/g_n = o(1) \). We write \( f_n = O(g_n) \) and \( g_n = \Omega(f_n) \) if there exists a constant \( C > 0 \) such that \( |f_n| \leq C |g_n| \) for all \( n \). We write \( f_n = \Theta(g_n) \) if \( f_n = O(g_n) \) and \( g_n = O(f_n) \). We write \( f_n \approx O(g_n) \) to indicate that the constant \( C \) above may depend on \( d \).}
We outline in §4.7 the necessary adaptations required in order to show that also in this case
\( P \) is a transition matrix of the LSRW on \( G \). By Fact 4.8 indeed we have that
\( t_s(G) \leq C d^2 (\log n)^2. \)

For the cycle \( t_s = \Theta((\log n)^2) \). This shows that (2.1) is sharp up to a factor \( O(\log n) \),
when \( d = O(1) \). We believe that the cycle is in some sense extremal for the SN model
(see Remark 8.6, Theorem 3 and Conjecture 8.2 for more details on this point).

The next remark discusses the case in which the particle density is considered as a
parameter of the model.

**Allowing the particle density to vary:** One may consider the case in which the density
of walkers at each site is multiplied by some \( \lambda > 0 \) (i.e. for all \( v \in V \) the number of
particles initially occupying \( N_v \) has a Poisson(\( \lambda n \)) distribution). Let \( \xi := 1_G \) is not regular.
For \( C_d \log |V|/|E| \leq \lambda \leq 1 \) one minor adaptations to the arguments from §4 are necessary
in order to show that
\[
\text{w.h.p. } \quad \text{SC}(G) \leq C d \lambda^{-4} (\log |V|)^3,
\]
(here we allow \( \lambda \) to depend on \( |V| \), provided that \( \lambda \geq C (\log |V|/|E|)^{\xi} \)). With additional work
this can be improved to w.h.p. \( \text{SC}(G) \leq C d^{1+5\xi} \lambda^{-2} (\log |V|)^3 \). When \( \lambda \in [\log |V|^{-1+\varepsilon}, 1] \) for
some \( \varepsilon \in (0,1) \), this is optimal up to an \( O_{d,\varepsilon}(\log |V|) \) factor as described in Remark 2.1.

When \( G \) is vertex-transitive (see Definition 8.1) we conjecture that
\[
E_{\lambda}[\text{SC}(G) | \text{there are at least two walkers}]
\]
is monotone decreasing in \( \lambda \) (see Conjecture 8.3 for a slightly different formulation).

It is not hard to extend the proofs of (2.2) and (2.3) to the case that the particle
density at each site is multiplied by some \( \lambda \in [\log |V|^{-\varepsilon}, 1] \) for some \( \varepsilon \in (0,1/2) \). In this case,
the lower bound on \( \text{SC}(G) \) is increased by a factor of \( \lambda^{-1} \). Similarly, one can extend (2.4)
as follows: if \( G = (V,E) \) is a connected \( n \)-vertex regular graph and \( \lambda \in [n^{-\varepsilon}, 1] \) for
some \( \varepsilon \in (0,1/16) \) then w.h.p. \( \text{SC}(G) \geq s_s(G,\lambda) := \min\{t : \frac{t+1}{s_{t+1}} > \frac{1}{232} \log n \}. \)

**Other initial distributions:** We may consider the case that initially each vertex is
occupied by a single particle. Consider the case that \( G \) is a \( d \)-regular Eulerian graph.
We outline in §4.7 the necessary adaptations required in order to show that also in this
setup we have
\[
\text{w.h.p.}^4 \quad \text{SC}(G) \leq C d (\log |V|)^3. \tag{2.5}
\]

**Extremality of the complete graph:** We will prove Theorem 2 for an arbitrary holding
probability \( p \in [0,1) \) for the walks (i.e. the probability of a walker staying put at each
given step is \( p \)). Let \( K_n \) be the complete graph on \( n \) vertices. Consider the SN model
on \( K_n \) with some holding probability \( p_n \in [0,1/n] \). It is not hard\(^3\) to verify that \( \text{SC}(K_n) \)
is concentrated around \( \log n \) in a window whose width is of order 1. Thus, by (2.3) the
complete graph is the regular graph with (asymptotically) the fastest social connectivity
time (at least when the holding probability is between 0 and \( 1/(d+1) \)).

**Extensions:** In §8 we discuss some extensions of our results (e.g. allowing the walkers
to belong to different communities, walking on different graphs with the same vertex set).

---

\(^4\)We say that a sequence of events \( A_n \) defined with respect to some probabilistic model on a sequence
of graphs \( G_n := (V_n,E_n) \) with \( |V_n| \to \infty \) holds w.h.p. ("with high probability") if the probability of \( A_n \) tends to
1 as \( n \to \infty \).

\(^3\)The proof is similar to the proof that the connectivity threshold for \( G(n,p) \), the Erdős and Rényi random
graph, occurs in a window of order \( 1/n \) around \( p_m = (\log n)/n \) (for the SN model the proof is still elementary,
but it is somewhat tedious and thus omitted).

EJP 24 (2019), paper 32.
http://www.imstat.org/ejp/
2.3 The n-cycle and higher dimensional tori

**Theorem 3.** Let \( C_n \) be the n-cycle. Consider the setup in which at time 0 there is exactly one walker at each vertex and that the walkers perform continuous-time independent SRWs (with jump rate 1). Then there exist some absolute constants \( c_1, c_2, \alpha, C_1, C_2 \) such that

\[
P[\text{SC}(C_n) > C_1 \log^2 n] \leq C_2/n. \tag{2.6}
\]

\[
P[\text{SC}(C_n) < c_1 \log^2 n] \leq e^{-c_2 n}. \tag{2.7}
\]

The proof of (2.6) is due to Gady Kozma. We thank him for allowing us to present his argument. Working in continuous-time simplifies the analysis of (2.6). The proof in the usual setup of \( \text{Pois}(1) \) walkers per site is in fact simpler (see Remark 6.1). As mentioned after Theorem 2, in the usual Poison, discrete-time setup (2.7) follows from (2.4).

**Remark 2.1.** When initially the number of particles per site is \( \text{Pois}(\lambda) \) distributed (independently for different sites) it is possible to extend the analysis of Theorem 3 in order to show that w.h.p. \( c < \frac{\text{SC}(C_n)}{\max(\lambda^{-1} \log(\lambda n)^{s}), 1} \leq C \) as long as \( \lambda \gg \frac{1}{n} \) (cf. [5] for the analysis of the frog model on the n-cycle for \( \lambda \gg n^{-1} \)).

**Remark 2.2.** Denote the d-dimensional torus of side length \( n \) by \( T_d(n) \). This is the Cayley graph of \( (\mathbb{Z}/n\mathbb{Z})^d \) obtained by connecting by an edge each \( x, y \in (\mathbb{Z}/n\mathbb{Z})^d \) which disagree only in one coordinate, by \( \pm 1 \) mod \( n \). Then \( T_1(n) \) is the n-cycle. We comment that using similar ideas as in [5, Theorem 2] one can show that w.h.p. \( c < \frac{\text{SC}(T_2(n))}{\log n \log \log n} < C \) and \( c < \frac{\text{SC}(T_d(n))}{\log n} < C \) for \( d \geq 3 \). This result appeared in an earlier version of this work. Note that \( \text{SC}(T_2(n)) \geq c \log n \log \log n \) and \( \text{SC}(T_d(n)) \geq (1 - o(1))d \log n \) w.h.p. follow from (2.4)-(2.3).

2.4 Expanders

We denote by \( \gamma(G) \) the spectral-gap of LSRW on \( G \), defined as the smallest non-zero eigenvalue of \( I - P \), where \( P \) is the transition matrix of LSRW on \( G \) and \( I \) is the identity matrix. We say that a sequence of graphs \( G_n \) is an expander family if \( \inf_n \gamma(G_n) \geq 0 \). We say that \( G \) is a \( \gamma \)-expander if \( \gamma(G) \geq \gamma \) (we think of \( \gamma \) as being uniformly bounded away from 0, independently of the size of \( G \), although our analysis remains valid even if this fails). The following result demonstrates that Theorem 2 is sharp.

**Theorem 4.** Let \( G \) be a connected \( d \)-regular \( n \)-vertex \( \lambda \)-expander. Then there exist absolute constants \( C, C', C_0 \) such that if \( \lambda \log_d n \geq C_0 \), then \( \text{SC}(G) \leq C \lambda^{-1} \log n \) w.p. at least \( 1 - C'/n \).

**Theorem 5.** Let \( G \) be a connected \( d \)-regular \( n \)-vertex \( \lambda \)-expander. Then there exist absolute constants \( \alpha, C_1 > 0 \) such that with probability at least \( 1 - \exp(-c d^{-1}n^s) \), where \( s := \lceil C_1/\lambda \rceil \), there is a class of walkers of size at least \( n/6 \).

We refer to a class of walkers in the SN model on some graph \( G = (V, E) \) at a certain time (of size \( \Omega(|V|) \)) as a giant class. We shall deduce Theorem 4 from Theorem 5 by bounding SC by the time it takes the giant class from Theorem 5 to "capture" the rest of the walkers. The requirement \( \lambda \log_d n \geq C_0 \) in Theorem 4 is imposed in order to ensure that the error term \( \exp(-c d^{-1}n^s) \) from Theorem 5 is small.

2.5 Organization of this work

In §3 we present some preliminaries. In §4 we prove (2.1). In §5 we prove (2.2) and Theorem 2. In §6 we prove Theorem 3. In §7 we study the SN model on expanders and prove Theorems 4-5. We conclude with some open problems, conjectures and concluding remarks in §8.
2.6 Related work and connections to other models

The social network model on infinite graphs is investigated in [10]. The setup studied in [10] is as follows. Given an infinite connected regular graph $G = (V, E)$, place at each vertex $\text{Pois}(\lambda)$ walkers performing independent lazy simple random walks on $G$ simultaneously. When two walkers visit the same vertex at the same time they are declared to be acquainted. It is shown in [10] that when $G$ is vertex-transitive and amenable, for all $\lambda > 0$ a.s. every pair of walkers will eventually have a path of acquaintances between them. In contrast, it is shown that when $G$ is non-amenable (not necessarily transitive) there is always a phase transition at some $\lambda_c(G) > 0$. General bounds on $\lambda_c(G)$ are given and the case that $G$ is the $d$-regular tree $T_d$ is studied in more detail (it is shown that $c \leq \lambda_c(T_d)/\sqrt{d} \leq C$). Finally, it is shown that in the non-amenable setup there exists a finite time $t$ such that a.s. there exists an infinite set of walkers having a path of acquaintances between them by time $t$. We note that the last result is the infinite setup counterpart of our Theorem 5.

We believe that, in spirit, the results in this paper should be true also for some other particle systems involving independent random walks. The $A + B \rightarrow 2B$ family of models [14, 15], often interpreted as models for a spread of an epidemic/rumor, are defined by the following rule: there are type $A$ and $B$ particles occupying a graph $G$, say with densities $\lambda_A, \lambda_B > 0$. They perform independent SRW with holding probabilities $p_A \in [0, 1]$ and $p_B \in [0, 1]$. When a type $B$ particle collides with a type $A$ particle, the latter transforms into a type $B$ particle. The frog model is the particular case of the above dynamics in which the type $A$ particles are immobile ($p_A = 1$) and $\lambda_A = \lambda_B = \lambda$.

We now consider a variant of the above model which is intimately related to the SN model. Consider the case in which initially only the particles at some vertex $o$ are of type $B$ and an additional $B$ particle is planted at $o$ (this is done to ensure that there is at least one $B$ particle). Consider the case that each $B$ particle performs only $t$ steps of its walk before vanishing (after which it cannot become reactivated again). We call $t$ the lifetime of the $B$ particles. We say that the process dies out when there are no $B$ particles left. One then defines the susceptibility, $S(G)$ as the minimal lifetime which is sufficient so that all particles are transformed into type $B$ particles before the process dies out (to make this definition formal, we think of the particles as first picking the infinite trajectory of their random walks, but then, once transforming into a $B$ particle, performing only $t$ additional steps of their walk). In the interpretation of the model as a model for a spread of a rumor/epidemic the susceptibility is meant to capture “how long should a virus live in order to infect the entire population” or “how interesting should a rumor be, so that eventually everybody will hear it”. Similarly, one can consider the minimal lifetime required so that every vertex is visited by at least one $B$ particle.

In [9, 5] parallel results to Theorems 2,3,4 and 5 are proved for the above variant in the case of the frog model, where the susceptibility replaces the social connectivity time. We strongly believe that (certain variants of) Theorems 2,3,4 and 5 should hold even when the $A$ particles are mobile. Moreover, we have the following conjecture concerning an analog of Theorem 1.

**Conjecture 2.3.** Consider the aforementioned variant of the $A + B \rightarrow 2B$ model with $\lambda_A = \lambda_B = \lambda$ and some fixed $p_A \in [0, 1]$ and $p_B \in (0, 1)$. Then there exist some $C_{d, \lambda}, \ell > 0$, such that for every sequence of finite connected graphs $G_n = (V_n, E_n)$ with $|V_n| \rightarrow \infty$ of maximal degree at most $d$, we have that

$$\lim_{n \rightarrow \infty} \mathbb{P}_\lambda \left[ S(G_n) / c_d, \lambda \log^\ell |V_n| \right] = 1.$$
3 Preliminaries and additional notation

3.1 Reversibility, stationarity of the occupation measure and independence of the number of walkers performing different walks.

Let $G = (V, E)$ be an Eulerian digraph. Let $P$ be the transition kernel of LSRW on $G$. We denote by $P^t(u, v)$ the $t$-steps transition probability from $u$ to $v$. We now establish a certain independence property for walks in $G$, which in particular implies a certain stationarity property of the SN model. Recall that $\pi_v := d_v/|E|$ and $\pi = |V|\pi$. For LSRW on a graph $G$ reversibility is the property that for every $v, u \in V$ and $t \geq 0$,

$$\pi_v P^t(v, u) = \pi_u P^t(u, v).$$

A walk of length $k$ in $G$ is a sequence of $k + 1$ vertices $(v_0, v_1, \ldots, v_k)$ such that for all $0 \leq i < k$ either $v_i = v_{i+1}$ or $(v_i, v_{i+1}) \in E$ (or for a graph $\{v_i, v_{i+1}\} \in E$). Let $\Gamma_k$ be the collection of all walks of length $k$ in $G$. For a walk $\gamma = (\gamma_0, \ldots, \gamma_k) \in \Gamma_k$ for some $k \geq 1$, let

$$p(\gamma) := \prod_{i=0}^{k-1} P(\gamma_i, \gamma_{i+1}) \quad \text{and} \quad q(\gamma) := \pi_0 p(\gamma).$$

Note that $p(\gamma)$ is precisely the probability that a walker whose starting position is $\gamma_0$ performed the walk $\gamma$ (i.e. her position at time $t$ is $\gamma_t$ for all $i \leq k$). Let $\gamma'$ be the reversal of $\gamma$ (i.e. $\gamma'_i = \gamma_{k-i}$ for all $i \leq |\gamma|$). Reversibility is equivalent to the following condition:

$$q(\gamma) = q(\gamma'), \quad \text{for every walk } \gamma.$$

We denote the number of walkers who performed a walk $\gamma$ by $X_\gamma$. We denote the number of walkers whose position at time $t$ is $v$ by $Y_v(t)$. Since $\pi$ is the stationary distribution of the walks, $E[Y_v(t)] = \sum_{u \in V} \pi_u P^t(u, v) = \pi_v$. Thus, for every fixed $t > 0$, we have that $Y_v(t)$ are independent and that $Y_v(t) \sim \text{Pois}(\pi_v)$ for $v \in V$.

3.2 Concentration inequalities

We shall use the following concentration estimate. Let $Y \sim \text{Pois}(\mu)$. Then

$$\forall a \geq 0, \quad \max \{P[Y \geq \mu + a], P[Y \leq \mu - a]\} \leq \exp \left( -\frac{a^2}{2(\mu + a/3)} \right).$$

By taking an appropriate limit, this follows from Bernstein’s inequality which says that if $\xi_1, \ldots, \xi_m$ are independent Bernoulli r.v.'s, $Y = \sum_{i \in [m]} \xi_i$, $\mu = E[Y]$ and $\sigma^2 = \text{Var}(Y)$, then

$$\forall a \geq 0, \quad \max \{P[Y \geq \mu + a], P[Y \leq \mu - a]\} \leq \exp \left( -\frac{a^2}{2(\sigma^2 + a/3)} \right).$$

Another concentration estimate which we shall use in the proof of some of the lower bounds on SC is the McDiarmid’s inequality, which we now state. Let $f : \mathcal{X}^n \to \mathbb{R}$. Let $c_i := \sup_{x, y} |f(x) - f(y)|$, where the supremum is taken over all $x := (x_1, \ldots, x_n), y := (y_1, \ldots, y_n) \in \mathcal{X}^n$ such that $x_j = y_j$ for all $j \neq i$. Let $X_1, \ldots, X_n$ be i.i.d. $\mathcal{X}$ valued r.v.'s. Then

$$P[f(X_1, \ldots, X_n) < E[f(X_1, \ldots, X_n)] - \varepsilon] \leq \exp \left( -\frac{2\varepsilon^2}{\sum_{i \in [n]} c_i^2} \right).$$
### 3.2 Negative association

Let $G = (V, E)$ be a finite Eulerian digraph. The goal of this subsection is to formulate the intuitive notion that given a certain deterministic initial configuration of walkers, a time $t > 0$ and a vertex $x$, the more walkers there are at $x$ at time $t$, the less walkers we expect to find at the other vertices of $G$.

The partial order $\preceq$ on $Z^V_+$ is defined as follows. For $a, b \in Z^V_+$ we have that $a \preceq b$ if $a(v) \leq b(v)$ for all $v$. We say that a function $f : Z^V_+ \to \mathbb{R}$ is increasing (resp. decreasing) if $f(a) \leq f(b)$ whenever $a \preceq b$ (resp. whenever $b \preceq a$, equivalently, $-f$ is increasing).

Let $X_1 := (X_1(v))_{v \in V}$ and $X_2 := (X_2(v))_{v \in V}$ be random elements in $Z^V_+$. Denote their laws by $\mu_1$ and $\mu_2$, respectively. We say that (the law of) $X_1$ stochastically dominates (the law of) $X_2$ if $\int f \, d\mu_2 \leq \int f \, d\mu_1$ for all increasing $f$. We say that $f : Z^V_+ \to \mathbb{R}$ depends only on the co-ordinates in $A$ if $f(z) = f(z')$ whenever $z(a) = z'(a)$ for all $a \in A$. We say that $Y := (Y(v))_{v \in V}$ are negatively associated if for every two disjoint sets $A, B \subseteq V$ and any two increasing functions $f, g$ such that the former depends only on the co-ordinates in $A$ and the latter depends only on the co-ordinates in $B$ we have that $E[f(Y)g(Y)] \leq E[f(Y)]E[g(Y)]$. It is immediate from the definition that if $(Y(v))_{v \in V}$ are negatively associated then:

1. The law of $(Y_u)_{u \neq v}$ stochastically dominates its conditional law given $Y_v > 0$ (take above $A = \{v\}$, $B = V \setminus \{v\}$ and $f = 1_{\{Y_v \geq 1\}}$).
2. $(Y(v))_{v \in V}$ are negatively correlated, i.e. $E[Y_i Y_u] \leq E[Y_i]E[Y_u]$, for all $u \neq v$.
3. If $V = [n]$ then for all increasing (resp. decreasing) $f_1, \ldots, f_n : Z_+ \to \mathbb{R}$ we have that
   \[
   E[\prod_{i \in [n]} f_i(Y_i)] \leq \prod_{i \in [n]} E[f_i(Y_i)].
   \]

The following result is due to Dubhashi and Ranjan [7, Theorem 13].

**Fact 3.2.** Let $X_1, \ldots, X_n$ be independent $[n]$ valued random variables. For $i \in [n]$ let $Y_i := \sum_{j \in [n]} 1_{\{X_j = i\}}$ be the number of $X_i$’s which take the value $i$. Then $(Y_i)_{i \in [n]}$ are negatively associated.

### 4 A general upper bound on SC - proof of (2.1)

In this section we prove (2.1), which is the harder and more interesting part of our main result, Theo

rem 1. Throughout the section we fix some connected $n$-vertex Eulerian digraph $G = (V, E)$ of average degree $d$ and set

\[
\ell := t_{d, |V|} := \lceil Cd^{1/\alpha} \text{ is not regular} \rceil \log n
\]

(4.1) for some sufficiently large absolute constant $C$ to be determined later.

#### 4.1 An overview of the proof

We first describe an easy auxiliary baby model (§4.2) and analyze it (Lemma 4.2). We then (§4.3) define the notions of a marginally $(\alpha, t)$-merging configuration, a globally $(\alpha, p, t)$-merging configuration and a $(\delta, t)$-balanced configuration (Definition 4.3) and explain how the analysis of the SN model can be reduced to that of the auxiliary baby model, assuming one of the first two properties hold at each given time w.h.p. (Proposition 4.7). Finally, in §4.4 we show that at each given time w.h.p. the configuration is $(1/8, t)$-balanced, and that this implies that it is marginally $(\alpha, t)$-merging for some $\alpha = \alpha_q$. 

EJP 24 (2019), paper 32. http://www.imstat.org/ejp/
4.2 Auxiliary baby models

Consider an arbitrary discrete-time coalescent process starting with \( m \) distinct classes. Define the coalescence time \( CT \) as the minimal time in which there is only one class (if there is no such time it is defined to be \( \infty \)). We now describe several simple coalescence models, and derive upper bounds on the coalescence time in each model. We intentionally start with two simple models, each involving a deterministic condition, and then work our way towards a slightly more complicated model which is more faithful to the actual details of our argument for the SN model.

Clearly, if prior to \( CT \) in every time unit every class merges with at least one other class, then deterministically, it must be the case that \( CT \leq \lceil \log_2 m \rceil \). We now generalize this simple model, while introducing some terminology which will be used throughout the section.

**Definition 4.1.** Fix some \( t > 0 \). Let \( t_k := kt \). We call the time interval \((t_k, t_{k+1}]\) the \((k+1)\)-th round. We say that the \((k+1)\)-th round is a \( p \)-merging round if either
\[
t_k \geq CT \quad \text{(this case is taken for technical reasons)} \quad \text{or} \quad t_k < CT \quad \text{and at least a} \quad p \quad \text{-fraction of the classes (w.r.t. time} \quad t_k \text{) have merged with at least one other class by the end of time} \quad t_{k+1}.
\]

The last definition makes sense for the SN model, as well as for a general coalescence model. Note that if the number of classes at the beginning of a \( p \)-merging round is \( \ell \geq 1 \), then the number of classes at the end of the round is at most \((1-p/2)\ell\). Assume that initially there are at most \( m \) classes. If all rounds are \( p \)-merging then, deterministically, \( CT \leq \lceil C_p t \log m \rceil \) (for concreteness, \( C_p := 1/\log(\frac{2p}{1-p}) \)). More generally, even if not all rounds are \( p \)-merging, there can be at most \( \lceil C_p \log m \rceil \) \( p \)-merging rounds prior to \( CT \). This motivates the following simple model in which each round is \( p \)-merging with probability at least \( \alpha \), regardless of the history. We intentionally keep the description and analysis of this model somewhat informal, deferring a more rigorous statement to Lemma 4.2.

**Simplified baby model:** Start with \( m \) classes. At each round flip a coin with heads probability at least \( \alpha \) (i.e. the heads probability in each round may depend on the history up to that time, but is guaranteed to be at least \( \alpha \)). If it lands on heads then the round is \( p \)-merging. The list of pairs of classes which merge with one another in each round (given the evolution of the model up to the beginning of the round and the result of the coin flip corresponding to the round) is determined according to some arbitrary predetermined rule (satisfying that whenever the coin lands on heads the requirement of being \( p \)-merging is satisfied by the list of pairs of merged classes), perhaps using some additional independent source of randomness. The predetermined rule can be thought of as one decided by an adversary.

It is intuitively clear that there exists \( C_{\alpha,p} \) of the form \( C_{\alpha,p} = K_1 C_p / \alpha \leq K_2 \) (for some sufficiently large absolute constants \( K_1, K_2 \), where \( C_p \) is as above) such that the probability that the total number of rounds exceeds \( L = L_{m,\alpha,p} := \lceil C_{\alpha,p} \log m \rceil \) tends to 0 as \( m \to \infty \). Informally, one can argue that the number of \( p \)-merging rounds in the first \( L \) rounds, stochastically dominates the Bin\((L, \alpha)\) distribution and then apply an appropriate large deviation estimate in order to bound \( P[\text{Bin}(L, \alpha) < C_p \log m] \).

**The auxiliary baby model:** We now consider another small variation of the last model by introducing an error term \( \varepsilon_m \). We refer to this variation as the auxiliary baby model. Consider the case that at each round with probability we only have probability \( \geq 1 - \varepsilon_m \), for some \( \varepsilon_m = o(1/\log m) \), that the model evolves according to the above description (i.e. like the "simplified baby model"), while with the complement probability it stops evolving (i.e. the coalescence process is terminated). It is intuitively clear that the conclusion from the previous paragraph remains valid, with an additional error term
Rapid social connectivity

of \( \epsilon_m L = o(1) \) for the probability that the number of rounds exceeds \( L \). We will show that the analysis of the SN model on an Eulerian graph \( G = (V, E) \) of average degree \( d \) can be reduced to that of the auxiliary baby model (for a suitable choice of parameters).

Observe that above it was sufficient to consider the number of classes at the end of each round in order to bound \( CT \) from above. This motivates the following lemma, which formulates rigorously the assertions made in the previous paragraphs. One should think of \( J_k \) below as the number of classes at the end of the \( k \)-th round, and so \( T_0 := \inf\{k : J_k = 0\} \) corresponds to the coalescence time \( CT \).

**Lemma 4.2.** Let \( J_k \) be a non-increasing \( \mathbb{Z}_+ \)-valued random process, measurable w.r.t. filtration \((\mathcal{F}_k)_{k \geq 0} \), with \( J_0 \leq m \), satisfying that for some \( 0 < \alpha, p, \epsilon_m < 1 \), for each \( k \) there exists some events \( A_k \in \mathcal{F}_k \) with \( P(A_k) \geq 1 - \epsilon_m \) satisfying that

\[
E[1_{\{J_{k+1} \leq (1-p/2)J_k\}} 1_{A_k} | \mathcal{F}_k] \geq \alpha 1_{A_k}.
\]  

(4.2)

Let \( T_0 := \inf\{k : J_k = 0\} \). Then there exists some constant \( C_{\alpha, p} \leq K/(\alpha p) \) such that

\[
P[T_0 > [C_{\alpha, p} \log m]] \leq m^{-2} + \epsilon_m([C_{\alpha, p} \log m] + 1).
\]

The proof of Lemma 4.2 follows by noting that by (4.2) \( M_k := (1 - \frac{1}{2} \alpha p)^k J_k 1_{J_k \leq (k/\alpha)|A_i|} \) is a supermartingale and \( P[T_0 > k] = E[M_k 1_{J_k \leq (k/\alpha)|A_i|}] \leq (1 - \frac{1}{2} \alpha p)^k E[M_0] + \epsilon_m k \).

The details are given in the appendix in §A.2.

### 4.3 Reducing the SN model to the baby model via merging configurations

We are interested in reducing the SN model to the auxiliary baby model. Recall that \( Y_v(s) \) is the number of walkers at vertex \( v \) at time \( s \). It is beneficial to consider a notion of “independence of the history” which depends only on \((Y_v(s))_{v \in V}\), whose distribution is stationary and hence convenient to work with, rather than also on the identity of the classes of walkers at time \( s \), which might have a complex dependency structure. This motivates the following key definitions.

**Definition 4.3.** Let \( Y := (Y_v)_{v \in V} \in \mathbb{Z}_+^V \). We identify \( Y \) with a configuration of walkers in which for each \( v \in V \) there are initially \( Y_v \) particles at \( v \). The walkers then perform a LSRW on \( G \) of length \( t \), where \( t \) is as in (4.1).

- Let \( \mathcal{P} \) be a partition of the walkers into (disjoint) sets \( A_1, \ldots, A_m \) with \( m \geq 2 \). We say that \( \mathcal{P} \) respects vertices if walkers which initially occupy the same vertex all belong to the same set in the partition (i.e. for all \( v \), each \( A_i \) contains either all \( Y_v \) walkers initially occupying \( v \) or none of them).

- We say that the configuration \( Y \) is marginally \((\alpha, t)\)-merging, if the following holds. For every vertex-respecting partition of the walkers into sets, \( A_1, \ldots, A_m \) with \( m \geq 2 \), for each \( A_i \) which contains less than half of the walkers, the probability that at least one walker from \( A_i \) will meet some walker not belonging to \( A_i \) by time \( t \) is at least \( \alpha \). We say such a configuration is globally \((\alpha, p, t)\)-merging if for every vertex-respecting partition of the walkers into sets, \( A_1, \ldots, A_m \) with \( m \geq 2 \), we have that with probability at least \( p \), there are at least \( \alpha (m - 1) \)’s such that at least one walker from \( A_i \) met by time \( t \) some walker not belonging to \( A_i \).

- We say that the configuration \( Y \) is \((\delta, t)\)-balanced, if for all \( v \in V \) we have that

\[
\sum_{u \in V} Y_u P^t(u, v) \geq (1 - \delta) \bar{\pi}_v \quad \text{recalling that} \quad \bar{\pi}_v := |V| \pi_v,
\]  

(4.3)

and

\[
\max_{u \in V} Y_u/d_u \leq \log |V|.
\]  

(4.4)
We say that the configuration $Y$ is fully $(\delta, t)$-balanced, if it is $(\delta, t)$-balanced and in addition $\sum_{u \in V} Y_u \pi^t(u, v) < (1 + 2\delta)\pi_v$ for all $v \in V$.

We believe that some of the ideas from the proof of (2.1) and in particular the notion of balanced configurations can be useful for other particle systems. For instance, the approach taken in [11], where the mixing time of the exclusion process on regular graphs is bounded from above in terms of the mixing of independent random walks, was greatly inspired by the proof of (2.1).

Throughout, we take $\delta$ to be some constant in $(0, 1/8)$. We now record the fact that requirement (4.4) holds w.h.p. when $(Y_u)_{u \in V}$ are independent and $Y_u \sim \text{Pois}(\bar{\pi}_u)$.

**Lemma 4.4.** Let $(Y_u)_{u \in V}$ be independent and $Y_u \sim \text{Pois}(\bar{\pi}_u)$. Then

$$P[\max_{u \in V} Y_u / d_u > \log |V|] \leq \sum_{u \in V} C \left( \frac{e}{\log |V|} \right)^{d_u \log |V|}.$$ 

**Proof:** $P[\text{Pois}(\bar{\pi}_u) > d_u \log |V|] \leq P[\text{Pois}(d_u) > d_u \log |V|] \leq CP[\text{Pois}(d_u) = \lfloor d_u \log |V| \rfloor]$. Finally, apply a union bound over all $u \in V$. \qed

Consider the SN model viewed at integer multiples of $t$. Think of the time interval $(kt, (k + 1)t)$ as the $k$-th round (for $k = 0$ we take $[0, t]$ instead of $(0, t]$). Assume that the configuration at time $kt$ is globally $(\alpha, p, t)$-merging. Then the $k$-th round is $\alpha/2$ merging in the sense of Definition 4.1 w.p. at least $p$. In light of Lemma 4.2, in order to prove (2.1), we need to show that for some absolute constant $c_1$, at each given time the configuration is globally $(c_1/d^{1+1/\delta} \text{ is not regular}, c_1, t)$-merging, with probability at least $1 - |V|^{-2}$, where here $t$ is as in (4.1). This observation is recorded in Proposition 4.7 below.

A priori, it may appear difficult to determine that a configuration is either marginally $(\alpha, t)$-merging or globally $(\alpha, p, t)$-merging (for some $\alpha, p \in (0, 1)$), as the sets $A_1, \ldots, A_m$ from Definition 4.3 form an arbitrary vertex-respecting partition. On the other hand, the property of being $(\delta, t)$-balanced is more tractable as it is stated in terms of a (lack of) a large deviation behavior for the expected number of walkers occupying each site $t$ steps into the future, given the current configuration. We now explain the relations between the four properties of being $(\delta, t)$-balanced, fully $(\delta, t)$-balanced, marginally $(\alpha, t)$-merging and globally $(\alpha, p, t)$-merging.

To prove (2.1) we shall later show that (i) if $C$ from the definition of $t$ in (4.1) is taken to be sufficiently large then at each given time the configuration of walkers is fully $(\frac{1}{\delta}, t)$-balanced w.p. at least $1 - 2|V|^{-2} + C|V|^2(1 - \log |V|)$ and (ii) if $C$ is regular then a fully $(\frac{1}{\delta}, t)$-balanced configuration is globally $(c_1/d, c_1, t)$-merging for some absolute constant $c_1 > 0$.

Before proving (ii) we show that (iii) a $(\frac{1}{\delta}, t)$-balanced configuration is marginally $(c_1/d^{1+1/\delta} \text{ is not regular}, t)$-merging for some absolute constant $c_1 > 0$ and (iv) a marginally $(\alpha, t)$-merging configuration is globally $(\alpha/2, \alpha/4, t)$-merging (this is done in Corollary 4.6).

To prove (iv) we use the following simple lemma which asserts that a uniform lower bound on the marginal probabilities of certain $m$ events, implies a corresponding lower bound on the probability that a certain fraction of them occur. The first equation from the lemma follows by a straightforward application of the Paley–Zygmund inequality (e.g. [13, Lemma 4.1]). The second equation is the one-sided Chebyshev’s inequality.

**Lemma 4.5.** Let $\xi_1, \ldots, \xi_m$ be indicator random variables. Let $p_i := E[\xi_i]$, $p := \min_i p_i$, $S := \sum_{i=1}^m \xi_i$, $\mu := E[S]$ and $\sigma^2 := \text{Var}(S) = \sum_i p_i(1 - p_i) + 2\sum_{i,j: i < j} \text{Cov}(\xi_i, \xi_j)$. Then

$$P[S \geq pm/2] \geq P[S \geq \mu/2] \geq (\mu/2)^2/E[S^2] \geq \mu/(4m) \geq p/4. \quad (4.5)$$

EJP 24 (2019), paper 32. 
http://www.imstat.org/ejp/
Rapid social connectivity

\[ \forall c \geq 0, \quad P[S \geq \mu - c\sigma] \geq \frac{c^2}{1 + c^2}. \tag{4.6} \]

In particular, if \( \text{Cov}(\xi_i, \xi_j) \leq 0 \) for all \( i \neq j \) then \( \sigma^2 \leq \mu \) and so \( P[S < \frac{1}{2}\mu] \leq \frac{1}{4\sigma^2} \).

In our setup, (4.5) implies the following. Assuming that the configuration at time \( t_k = kt \) is marginally \( \alpha \)-merging and \( A_1, \ldots, A_m \) are the classes of walkers at time \( t_k \) (the classes clearly form a vertex-respecting partition of the walkers), then with probability at least \( \alpha/4 \), there exists an index set \( I \) of size at least \( \lceil \alpha(m - 1)/2 \rceil \) such that for all \( i \in I \) there is some walker from \( A_i \) who met in the time interval \((t_k, t_k + \ell] \) some walker not belonging to \( A_i \). We now record this observation.

**Corollary 4.6.** A marginally \((\alpha, t)\)-merging configuration is globally \((\alpha/2, \alpha/4, t)\)-merging.

**Proof.** The second assertion follows from the first via Corollary 4.6. For the first assertion, if we think of each interval of length \( t \) as a round, we have that at time \( kt \) the configuration of walkers is globally \((\alpha, p, t)\)-merging, then the \((k + 1)\)-th round (corresponding to the time interval \((kt, (k + 1)t] \) is \( \frac{\alpha}{4} \)-merging, in the sense of Definition 4.1, with probability at least \( p \) (this holds regardless of the outcomes of the previous rounds). Since at the beginning of each round w.p. at least \( 1 - \varepsilon_n \) the configuration of walkers is globally \((\alpha, p, t)\)-merging, we are precisely at the setup of the auxiliary model and the assertion of the proposition now follows from Lemma 4.2. \( \square \)

### 4.4 Proof of the validity of the marginally \((\alpha, t)\)-merging property via a reduction to the \((\delta, t)\)-balance condition

Note that if \((Y_v(s))_{v \in V}\) is distributed like the configuration of walkers in the SN model on \( G \) at time \( s \), then (by stationarity of the occupation measure, which allows one to consider only the case that \( s = 0 \)) for every \( v \in V \) the sum \( Z_v(s) := \sum u P^t(u, v) Y_u(s) \) in (4.3) (whose mean is \( \bar{\pi}_v \)) is a linear combination (with non-negative coefficients) of independent Poisson r.v.’s. As demonstrated in Lemma 4.10 below, in order to obtain a large deviation estimate for such a linear combination (namely, for the event \( Z_v(s) < (1 - \delta)\bar{\pi}_v = (1 - \delta)E[Z_v(s)] \)), it suffices to control the maximal coefficient \( P^t(u, v) \) appearing in the sum. We obtain such control using the following decay estimate for \( \max_{x,y} P^t(x, y) \).

Recall that \( d_y \) is the degree of vertex \( y \).

**Fact 4.8** ([6] Lemma 2.4). There exists an absolute constant \( M \) such that for every finite connected Eulerian digraph \( G = (V, E) \), LSRW on \( G \) satisfies

\[ \forall t \geq 1, \quad \max_{x,y} |P^t(x, y) - \pi_y| \leq M \sqrt{1/t}d_y 1_G \text{ is not regular} + 1_G \text{ is regular}. \tag{4.7} \]

In what comes, we shall assume that (\( \star \)) \( 12d_{G}^{2} \text{ is not regular} \leq \log |V| \leq \delta^2|E| \). Note that if (\( \star \)) fails, then \( |V| \) has to be bounded (recall that \( \delta \) is a constant and that \( |V|d = 2|E| \), as \( d \) is
the average degree). The following proposition, whose proof is deferred to §4.5 implies (2.1) when (*) fails.

**Proposition 4.9.** Let $G = (V, E)$ be a connected Eulerian digraph. Then for some $C > 0$,

$$P[SC(G) > C|E||V| \log |V|] \leq C/|V|.$$  

By Fact 4.8, if we set $C = 12M\delta^{-2}$ in the definition of $t$ ((4.1)) then

$$\max_{x,y} P^t(x, y) \leq \pi_y + \delta^2 d_y / (12d \log |V|).$$  

(4.8)

Assume (*) holds for some fixed $0 < \delta \leq 1/8$. By (4.8) we have that

$$\max_{x,y} P^t(x, y) \leq \delta^2 d_y / (6d \log |V|).$$  

(4.9)

In light of Lemma 4.4 and the paragraph following (4.3), by combining (4.9) with the following lemma, it follows by a union bound over the vertices of $G$ that the probability that the configuration is not $(\delta, t)$-balanced at some fixed time $s$ is at most $C_1/|V|^2$ (assuming (*), when the constants are chosen as indicated above).

**Lemma 4.10.** Let $\xi_1, \ldots, \xi_m$ be independent Poisson random variables. Let $p_1, \ldots, p_m \in (0, 1)$. Let $p_* := \max p_i$, $S := \sum_{i=1}^m p_i \xi_i$ and $\mu := E[S]$. Then for all $\varepsilon \in (0, 1)$

$$P[S \leq (1 - \varepsilon)\mu] \leq e^{-\frac{1}{2}\mu \varepsilon^2 / \mu^2}.$$  

(4.10)

The proof of Lemma 4.10 is given in the appendix in §A.1.

**Corollary 4.11.** Let $Y_v(s)$ be the number of walkers at vertex $v$ at time $s$. Assume that $Y_v(0) \sim \text{Pois}(\pi_v)$ independently for different vertices. Let $t$ be as above and assume that (*) holds. Let $n := |V|$ and $Z_v(s) := \sum_{u \in V} P^t(u, v)Y_u(s)$. Then for all $s \geq 0$ and $v \in V$ we have

$$P[Z_v(s) \leq (1 - \delta)\pi_v] \leq \exp \left[-\frac{\pi_v \delta^2}{2(6d \log n)/|V|^2}\right] \leq n^{-3}.$$  

$$P[Z_v(s) \geq (1 + 2\delta)\pi_v] \leq \exp \left[-\frac{\pi_v (2\delta)^2}{4(6d \log n)/|V|^2}\right] \leq n^{-6}.$$  

The following proposition concludes the proof of (2.1) when $G$ is not regular, and provides a version of (2.1) also for a regular $G$ which has a worse degree dependence than (2.1). Below we assume that the total number of walkers is at most $|V| + |V|^{2/3}$. By (3.2), the probability that this fails is at most $\exp(-\frac{1}{4}|V|^{1/3})$ and hence there is no harm in assuming this holds.

**Proposition 4.12.** Let $G = (V, E)$ be an $n$-vertex connected Eulerian digraph of average degree $d$. Let $\xi := 1[G \text{ is not regular}]$. Let $0 < \delta \leq 1/8$. Assume that (*) holds. Assume that a configuration of walkers is $(\delta, t)$-balanced for $t := \lceil 12d^2 M \delta^{-2} (\log n) \rceil^2$ and that the total number of walkers it contains is smaller than $n + n^{2/3}$. Then there exists some absolute constant $c > 0$ such that the following hold.

(i) The configuration is marginally $(\varepsilon/d^{1+\xi}, t)$-merging.

(ii) If $G$ is regular and $\{ (u, v) \in E : u \in A, v \notin A \text{ or } u \notin A, v \in A \} \geq c_0 d$ for every set $A \subset V$ such that $|A| \leq \frac{2}{3}(n + n^{2/3})$ then the configuration is marginally $(\varepsilon c_0, t)$-merging.
Rapid social connectivity

Proof. Consider some configuration \((X_v)_{v \in V}\) of walkers (i.e. for all \(v\) the number of walkers at vertex \(v\) is \(X_v\)) with at most \(n + n^{2/3}\) walkers (i.e. \(\sum_v X_v \leq n + n^{2/3}\)) and a vertex-respecting partition of the walkers into disjoint sets \(A_1, \ldots, A_m\). Since both the properties of a configuration which we consider (being marginally \((\alpha, t)\)-merging and \((\delta, t)\)-balanced) are independent of the time, by stationarity of the occupation measure w.l.o.g. we may assume that this configuration corresponds to time 0. We start with part (i).

Let \(\alpha_d := \tilde{c}/d^{1+\xi}\), where \(\tilde{c} > 0\) shall be determined soon. We now fix some \(1 \leq i \leq m\) such that \(|A_i| \leq (n + n^{2/3})/2\) and show that the probability that at least one walker from \(A_i\) meets some walker not from \(A_i\) by time \(t\) at least \(\alpha_d\). Denote the collection of vertices occupied by the walkers from \(A_i\) at time \(t\) by \(V_j\) (where \(1 \leq j \leq m\)). Denote the expected number of walkers from \(A_i\) (resp. not from \(A_i\), i.e. from \(\cup_{j \neq i} A_j\)) at vertex \(v\) at time \(t\) by

\[
\mu_v(j) := \sum_{u \in V_j} P^t(u, v) X_u, \quad \text{(resp. } a_v(i) := \sum_{i \neq j} \mu_v(i) = \sum_{i \neq j} \sum_{u \in V_i} P^t(u, v) X_u). \]

As \(\sum_{v \in V} \mu_v(j) = |A_i|\), there can be at most one set \(A_j\) with \(\mu_v(j) > (1 - 2\delta)\bar{\pi}_v\) for all \(v\) (assuming \(n \geq 8\); where we have used \(\delta \leq 1/8\) and \(\sum_v X_v \leq n + n^{2/3}\)). Hence we only have to treat the case that \(\mu_v(i) \leq (1 - 2\delta)\bar{\pi}_v\) for all \(v\) and the case that \(\mu_v(i) \leq (1 - 2\delta)\bar{\pi}_v\) holds for some of the vertices, but not for all.

Assume that \(\mu_v(i) \leq (1 - 2\delta)\bar{\pi}_v\) for all \(v\). Then since the configuration is \(\delta\)-balanced

\[
\forall v \in V, \quad a_v(i) \geq (1 - \delta)\bar{\pi}_v - \mu_v(i) \geq \delta \bar{\pi}_v = \frac{\delta d^i}{d}. \tag{4.11}
\]

An elementary calculation (see Lemma 4.13) now shows that for all \(v\) the probability that there is a walker not from \(A_i\) at \(v\) at time \(t\) is at least \(1 - e^{-a_v(i)}\). Hence trivially every walker from the set \(A_i\) has a chance of at least \(1 - e^{-a_v(i)}\) of meeting some walker not from \(A_i\) at time \(t\). In this case, the proof is concluded using (4.11).

Finally, assume that \(\mu_v(i) > (1 - 2\delta)\bar{\pi}_v\) for some \(v\) but not for all \(v\). We argue that in this case, there must be some vertex \(u\) such that for some absolute constant \(c_1 > 0\)

\[
c_1/d \leq u_v(i) \leq (1 - 2\delta)\bar{\pi}_v. \tag{4.12}
\]

Once this is established, the proof is concluded as follows. Let \(u\) be as above. Since the configuration is \((\delta, t)\)-balanced we have that

\[
a_u(i) \geq (1 - \delta)\bar{\pi}_u - u_v(i) \geq \delta \bar{\pi}_u.
\]

By (4.12) together with the elementary Lemma 4.13 below, the probability that \(u\) is occupied at time \(t\) by both a walker from \(A_i\) and also by a walker not from \(A_i\) is at least

\[
(1 - e^{-\mu_u(i)})(1 - e^{-a_u(i)}) \geq \frac{1}{4} \mu_u(i) a_u(i) \geq \frac{c_1}{4d} \delta \bar{\pi}_u \geq \tilde{c}/d^{1+\xi}. \tag{4.13}
\]

as desired (where we have used \(1 - e^{-x} \geq x - \frac{1}{2} x^2 \geq \frac{x}{2}\) for \(x \in [0, 1]\)). We now verify the existence of such \(u\) satisfying (4.12). Let

\[
D_i := \{v : \mu_v(i) \geq (1 - 2\delta)\bar{\pi}_v\}. \tag{4.14}
\]

We argue that if \(u \notin D_i\) and \((v, u) \in E\) for some \(v \in D_i\), then \(u\) satisfies (4.12) (by our assumption on \(A_i\), the set \(D_i\) is non-empty and is a proper subset of \(V\)). This follows from Lemma 4.14 below (whose proof is deferred to the appendix §4.3; See Remark 4.15 for the intuition behind this lemma), applied to the collection of walkers from \(A_i\) (i.e. take
Rapid social connectivity

$Y_v(0)$ in Lemma 4.14 to be 0 if the walkers which are at time 0 at vertex $y$ do not belong to $A_i$, otherwise take it to be the number of such walkers; Note that condition (4.4) from the definition of a $(\delta, t)$-balanced configuration implies that the term $E[Y_v(t)]$ from Lemma 4.14 is much smaller than the term $E[Y_v(t)]$.

We now prove part (ii). We now assume $G$ is regular, and so $\pi_v = 1$ for all $v$. We fix some $i$. The case that $\mu_v(i) \leq 1 - 2\delta$ for all $v$ is the same as before. We now treat the case that $\mu_v(i) > 1 - 2\delta$ for some $v$ but not for all $v$. We may assume that $|A_i| \leq \frac{1}{2}(n + n^{2/3})$, as there can be at most one class which contains more than half of the walkers. Let $D_i$ be as in (4.14). Observe that $|D_i| \leq \frac{|A_i|}{(1-2\delta)} \leq \frac{2}{5}(n + n^{2/3})$ (as $\delta \leq 1/8$) and so $\max\{|E_{\text{out}} D_i|, |E_{\text{in}} D_i|\} \geq \frac{c_d}{2}$, where $E_{\text{out}} A := \{(u, v) \in E : u \in A, v \notin A \}$ and $E_{\text{in}} A := \{(v, u) \in E : u \in A, v \notin A \}$. We first treat the case that $|E_{\text{out}} D_i| \geq c_d/2$.

For each $e = (v, u)$ let $Z_e$ be the indicator of the event that there is some walker from $A_i$ which was at $v$ at time $t - 1$ and then moved to $u$ at time $t$. Let $Z := \sum_{e \in E} Z_e$. As in the proof of part (i), by Lemma 4.14, there exists some $c > 0$ such that $E[Z_e] > c/d$ for all $e \in E_{\text{out}} D_i$. Hence $E[Z] \geq c_1 c_0$. By Fact 3.2 we have that $(Z_e)_{e \in E}$ are negatively correlated, and thus $\text{Var}(Z) \leq E[Z]$. Thus, using the one-sided Chebyshev’s inequality (4.6) we get that $P[Z > 0] \geq \frac{E[Z]}{E[Z]} \geq c_2 c_0$. Conditioned on $Z_e = 1$ for $e = (v, u)$ $\in E_{\text{out}} D_i$, as in the proof of part (i), the probability that there is a walker not from $A_i$ at $u$ at time $t$ is bounded from below (as $u \notin D_i$) and the configuration is $(\delta, t)$-balanced). This concludes the proof in the case that $|E_{\text{out}} D_i| \geq c_d/2$.

Now consider the case that $|E_{\text{in}} D_i| \geq c_d/2$. For each $e = (v, u)$ let $\hat{Z}_e$ be the indicator of the event that there is some walker from $\cup_{j \neq i} A_j$ which was at $v$ at time $t - 1$ and then moved to $u$ at time $t$. Let $\hat{Z} := \sum_{e \in E} \hat{Z}_e$. As in the proof of part (i), by Lemma 4.14, there exists some $c > 0$ such that $E[\hat{Z}_e] > c/d$ for all $e \in E_{\text{in}} D_i$. Hence $E[\hat{Z}] \geq c_1 c_0$. By Fact 3.2 we have that $(\hat{Z}_e)_{e \in E}$ are negatively correlated. Thus as before, using the one-sided Chebyshev’s inequality (4.6), we get that $P[\hat{Z} > 0] \geq c_2 c_0$. Conditioned on $\hat{Z}_e = 1$ for $e = (v, u) \in E_{\text{in}} D_i$, as in the proof of part (i), the probability that there is a walker from $A_i$ at $u$ at time $t$ is bounded from below (as $u \in D_i$).

Lemma 4.13. Let $\xi_1, \ldots, \xi_m$ be independent Bernoulli random variables. Denote $p_i := E[\xi_i]$, $S := \sum_i \xi_i$ and $\mu = E[S]$. Then $P[S = 0] = \prod_{i=1}^m (1 - p_i) \leq \exp[\sum_{i=1}^m -p_i] = e^{-\mu}$.

Lemma 4.14. Let $G = (V, E)$ be a finite Eulerian graph. Let $Y_v(t)$ be the number of walkers which occupy vertex $v$ at time $t$, where $(Y_v(0))_{v \in V}$ is some arbitrary deterministic initial configuration of walkers and different walkers perform independent LSRWs. Let $(v, u) \in E$. Let $Y := \max_{x \in V} \sum_{t=0}^\infty Y_v(0)$. Then

$$2d_v E[Y_v(t)] \geq E[Y_v(t - 1)] \geq \frac{1}{3} (E[Y_v(t)] - Y \exp(-c_1 t)).$$

(4.15)

Remark 4.15. The proof of Lemma 4.14 relies on laziness in a crucial manner (in fact, this is the only use of laziness in the proof of (2.1)). The idea is that typically a lazy walk of length $t$ makes at least $t/3$ lazy steps (the error term $\exp(-c_1 t)$ corresponds to the total contribution to $E[Y_v(t)]$ of the paths that make less than $t/3$ lazy steps). Such a walk could be transformed into many walks of length $t - 1$ with the same end-point by deleting one of the lazy steps. The “cost” of this operation is at most a constant factor (this uses the fact that there are at least $\Omega(t)$ lazy steps). In fact, some algebra yields that it is at most $\sup_{0 \leq k \leq t/3, t/3 \leq t} \left( \frac{1}{k} \right) \left( \frac{t}{k - 1} \right) \leq 3$.

4.5 Proof of proposition 4.9

Proof: By [6, Lemma 2.4] there exists some $C > 0$ such that for $t := \lceil C |E||V| \rceil$,

$$P^t(x,y) \geq \pi_y/2, \text{ for all } x,y \in V.$$
Rapid social connectivity

Hence, by independence, for every pair of walkers with some arbitrary initial positions we have that the probability that they are at the same position at time $t$ is at least $\sum_{x \in V} (\pi_x / 2)^2 \geq \frac{1}{\pi^2 t} \left( \sum_{x} \pi_x^2 \right)^2 = \frac{1}{\pi^2 t}$. We may assume that the total number of walkers $Y$ is greater than $3|V|/4$, as the probability that this fails is exponentially small in $|V|$.

Under this assumption, it follows from Lemma 4.5 that there exists some constant $\alpha > 0$ such that for every collection of $1 + \frac{1}{3}[3|V|/4]$ walkers with some arbitrary initial conditions, the probability that the first walker met at time $t$ one of the other walkers in the collection is at least $\alpha$. It follows that $(if \ Y > \frac{3|V|}{4})$ the configuration of walkers at each fixed time $s$, deterministically, has the $(\alpha, t)$-merging property. The proof is now concluded using Proposition 4.7. \hfill \Box

4.6 Proof of (2.1) for regular $G$

In this subsection we prove (2.1) when $G$ is regular. This is done by combining Proposition 4.16 below, which refines Proposition 4.12, with Proposition 4.7.

Let $G = (V, E)$ be a connected $d$-regular $n$-vertex Eulerian digraph. Let

$$t_*(G) := \max \left\{ \tilde{t}_*: \left[ \frac{2}{c_1} \log \log n \right] \right\},$$

where $\tilde{t}_* := \inf \left\{ t : \max_{x,y} |P^t(x, y) - \frac{1}{n}| \leq \frac{1}{3 \cdot 2^6 \log n} \right\}$.

The choice of the constant $3 \cdot 2^6$ was made so that by Corollary 4.11, provided that (*) holds for $\delta = 1/8$, we have that the configuration of walkers is $(\frac{1}{8}, t_*(G))$-balanced w.p. at least $1 - 2n^{-2}$. The choice of the constant $\frac{2}{c_1}$ was made to ensure that for a $(\frac{1}{8}, t_*(G))$-balanced configuration we have in Lemma 4.14 that $\mathbb{E}[Y_0(t)] - Y \exp(-c_1 t) \geq \frac{1}{2} \mathbb{E}[Y_0(t)]$.

In this subsection we improve Proposition 4.12 as follows.

**Proposition 4.16.** Let $G = (V, E)$ be a connected $d$-regular $n$-vertex Eulerian digraph satisfying (*) for $\delta = 1/8$. Assume that a configuration of walkers is fully $(\frac{1}{8}, t_*(G))$-balanced and that the total number of walkers it contains is smaller than $n + n^{2/3}$. Then there exists some absolute constant $c > 0$ such that the following hold.

(i) The configuration is globally $(\bar{c} / d, \bar{c}, t_*(G))$-merging.

(ii) If $|\{(u, v) \in E : u \in A, v \notin A \text{ or } u \notin A, v \in A\}| \geq c_0 d$ for every set $A \subset V$ such that $|A| \leq \frac{2}{3} (n + n^{2/3})$ then the configuration is marginally $(\bar{c} c_0, t_*(G))$-merging.

**Proof.** We first prove part (i). Consider some configuration $(X_v)_{v \in V}$ of walkers with at most $n + n^{2/3}$ walkers and a vertex-respecting partition of the walkers into disjoint sets $A_1, \ldots, A_m$. Again, we may think of the current time as being time 0. Let $a_u(i)$ (resp. $\mu_u(i)$) be the expected number of walkers not from (resp. from) $A_i$ which occupy $u$ at time $t_*(G)$. First consider the case that there is a set $I \subseteq [m]$ of size at least $(m - 1)/2$ such that for all $i \in I$ we have that $\mu_u(i) \leq \frac{1}{4}$ for all $u$. Then from the proof of Proposition 4.12 we see that for each $i \in I$ the probability that some walker from $A_i$ has met by time $t_*(G)$ some walker not from $A_i$ is at least $c_3 > 0$. By Lemma 4.5 we have that with probability at least $c_3/4$, there are at least $c_3 |I|$ sets $A_i$ with $i \in I$ such that some walker from $A_i$ has met by time $t_*(G)$ some walker not from $A_i$.

Now consider the case that there is a set $J \subseteq [m]$ of size at least $(m - 1)/2$ such that for all $j \in J$ we have that $\mu_u(j) \geq \frac{3}{4}$ for some $u \in V$ but not for all $v \in V$. For each $j \in J$,
Rapid social connectivity

as before, let $D_j := \{v : \mu_u(j) > \frac{1}{3}\}$. Let

$$F_j := \{v \in D_j : \text{there exists some } u \notin D_j \text{ such that } (u, v) \in E\}.$$  

For every $j \in J$ fix some $v_j \in F_j$. Observe that since the configuration is fully $(\frac{1}{3}, t_*(G))$-balanced we have that the sets $(F_j)_{j \in J}$ are disjoint, and so $(v_j)_{j \in J}$ are distinct.

Let $Z_j$ be the indicator of the event that some walker from $A_j$ and also some walker not from $A_j$ occupying $v_j$ at time $t_*$. As in the proof of Proposition 4.12 we have that $\mathbb{E}[Z_j] \geq c_3/d$. By Fact 3.2 we have that $(Z_j)_{j \in J}$ are negatively correlated (indeed, for $i \neq j$ knowing that $Z_i = 1$ decreases the chances of both the requirements for $Z_j = 1$). Hence by the one sided Chebyshev’s inequality (4.6) $\mathbb{P}([\sum_{j \in J} Z_j > \frac{c_3}{2^n} | J| ] \geq c_4 > 0$ as desired.

The proof of part (ii) is identical to the proof of part (ii) of Proposition (4.16).

\[ \square \]

4.7 Deterministic initial configuration

Let $G = (V, E)$ be a connected $d$-regular $n$-vertex Eulerian digraph. Consider the case that initially there is exactly one walker at each site and that the walkers perform independent LSRWs. Let $Y_v(s)$ be the number of particles occupying $v$ at time $s$. Let $t_*(G)$ be as in (4.16). Assume $n$ is sufficiently large so that $\frac{1}{n} \leq \frac{1}{d} \frac{1}{n \log n}$ (which by the definition of $t_*(G)$ implies that $\pi_{x,y} P_{t_*(G)}(x, y) \leq \frac{1}{d} \frac{1}{n \log n}$). We show that at each given time the configuration is fully $(\frac{1}{3}, t_*(G))$-balanced w.p. at least $2n^{-4 + n^{-\log n}}$. From this, as in the proof of (2.1), we get that w.h.p. $SC(G) \leq C dt_*(G) \log n \leq C d (\log n)^3$.

The proof of the following proposition is similar to that of Proposition 4.10. The main difference is that now the number of walkers at distinct vertices are not independent and thus one has to rely on (3.5) in order to bound $\mathbb{E}[\exp(\lambda Z_v(s))]$ from above.

**Proposition 4.17.** Let $Z_v(s) := \sum_{u \in V} Y_v(s) P_{t_*(G)}(u, v)$. In the above setup we have that

$$\forall s \geq 0, \quad \mathbb{P}\left[ Z_v(s) \notin \left( \frac{7}{8}, \frac{10}{8} \right) \right] \leq 2 n^{-4}. \quad (4.17)$$

$$\forall s \geq 0, \quad \mathbb{P}\left[ Y_v(s) \geq \log n \right] \leq n^{-\log n}. \quad (4.18)$$

**Proof:** Let $v \in V$ and $s \geq 0$ We first prove (4.17). Let $\lambda \in [-2^9 \log n, 2^9 \log n]$ to be determined later. By Fact 3.2 and (3.5) we have that

$$\mathbb{E}[\exp(\lambda Z_v(s))] = \mathbb{E} \prod_{u \in V} \exp(\lambda Y_u(s) P_{t_*(G)}(u, v))$$

$$\leq \prod_{u \in V} \mathbb{E}[\exp(\lambda Y_u(s) P_{t_*(G)}(u, v))]. \quad (4.19)$$

Note that $\exp(\lambda Y_u(s) P_{t_*(G)}(u, v)) = \prod_{y \in V} \exp(\lambda \xi_y(u, s) P_{t_*(G)}(u, v))$, where $\xi_y(u, s)$ is the indicator of the event that the walker which initially occupied $y$ is at $u$ at time $s$. Then

$$\mathbb{E}[\exp(\lambda Y_u(s) P_{t_*(G)}(u, v))] = \prod_{y \in V} \mathbb{E}[\exp(\lambda \xi_y(u, s) P_{t_*(G)}(u, v))]. \quad (4.20)$$

Let $p_\ast := \max\{ P_{t_*(G)}(x, y) : x, y \in V\} \leq \frac{1}{d \log n}$. As $|\lambda| p_\ast \leq 1$ and $e^x - 1 \leq x + \frac{x^2}{1 + e^x} \leq 0$ for $x \in [-1, 1]$ we get that for all $u, v \in V$ we have that

$$\mathbb{E}[\exp(\lambda \xi_y(u, s) P_{t_*(G)}(u, v))] - 1 \leq P^\ast(y, u) \left( e^{\lambda P_{t_*(G)}(u, v)} - 1 \right)$$

$$\leq P^\ast(y, u) \left[ \lambda P_{t_*(G)}(u, v) + \frac{\left( \lambda P_{t_*(G)}(u, v) \right)^2}{1 + \lambda \xi_y(u, s)} \right]$$

$$\leq P^\ast(y, u) \lambda P_{t_*(G)}(u, v) \left[ 1 + \frac{\lambda p_\ast}{1 + \lambda \xi_y(u, s)} \right].$$
We now prove (4.18). It suffices to prove the following. Let

\[ S \]

we get that

\[ \frac{\lambda^2 p_s}{2} \]

Taking \( \lambda = -\frac{1}{8p_s} \) and noting that \( P[Z_v(s) \leq \frac{7}{8}] = P[\exp(\lambda Z_v(s)) \geq e^{\frac{\lambda}{2}}] \) we see that

\[ P[Z_v(s) \leq \frac{7}{8}] = \exp(\lambda/8 + \frac{\lambda^2 p_s}{2}) = \exp(-\frac{1}{2p_s}) \leq n^{-4}. \]

Taking \( \lambda = \frac{1}{8p_s} \) and noting that \( P[Z_v(s) \geq \frac{10}{8}] = P[\exp(\lambda Z_v(s)) \geq e^{\frac{10\lambda}{2}}] \) yields

\[ P[Z_v(s) \geq \frac{10}{8}] \leq \exp(-\lambda/4 + \frac{\lambda^2 p_s}{2}) = \exp(-\frac{1}{2p_s}) \leq n^{-8}. \]

We now prove (4.18). It suffices to prove the following. Let \( \xi_1, \xi_2, \ldots, \xi_m \) be independent Bernoulli r.v.’s. Let \( p_i := E[\xi_i] \). Assume that \( \sum_i p_i = 1 \). Let \( L > 0 \) and \( \lambda = \log L \). Then

\[ P[S + 1 + L] \leq L^{-(L+1)}, \]

where \( S := \sum_i \xi_i \). Indeed \( E[e^{\lambda \xi_i}] = 1 + p_i(e^\lambda - 1) \leq \exp(p_i(e^\lambda - 1)) \). As \( E[e^{\lambda S}] = \prod_i E[e^{\lambda \xi_i}] \),

\[ P[S + 1 + L] \leq E[e^{\lambda S}]e^{-\lambda(1+L)} = \exp(e^\lambda - 1)e^{-\lambda(1+L)} \leq \exp(-(L + 1) \log L). \]

5 General lower bounds on the social connectivity time

Clearly we can bound SC from below by the minimal time by which every walker has met at least one other walker. This motivates the following definition.

**Definition 5.1.** We say that a walker remained isolated for time \( t \) if this walker has not met any other walkers up to and including time \( t \). We say that a walker is lazy by time \( t \) if this walker has not left her initial position by time \( t \). We denote the event that there is an isolated lazy walker at vertex \( v \) by time \( t \) by \( IL_v(t) \).

Recall that by elementary properties of the Poisson distribution, conditioned on the total number of walkers being \( m \), each of them independently starts at a random initial position chosen according to the stationary distribution. We denote the corresponding probability and expectation for the aforementioned initial condition by \( P^{(m)} \) and \( E^{(m)} \). In what comes, it will sometimes be convenient to condition on the total number of walkers.

**Proposition 5.2.** Let \( G = (V, E) \) be a finite Eulerian digraph of average degree \( d \) and minimal degree \( d_{min} \). Let \( m \in \mathbb{N} \). Let \( Z(t) := \sum_{v \in V} IL_v(t) \) be the number of isolated lazy walkers at time \( t \). Let \( Y(t) \) be the number of walkers which remained isolated for time \( t \). Then

\[ P^{(m)}[Y(t) = 0] \leq \exp\left(-\frac{2(E^{(m)}[Y(t)])^2}{m(t + 2)^2}\right). \]

\[ E^{(m)}[Z(t)] \geq m\pi\{v : \#_v \leq 2\} 2^{-t} \left(1 - \frac{2(t + 1)}{|V|}\right)^{m-1} \geq d_{min} \frac{2^d}{2d} m 2^{-t} \left(1 - \frac{2(t + 1)}{|V|}\right)^{m-1}. \]

In additional, if \( G \) is a regular graph then

\[ E^{(m)}[Y(t)] \geq m \left(1 - \frac{(2t + 1)/|V|}{\min_{v \in V} \sum_{i=0}^t P^{(m)}(v, v)}\right)^{m-1}. \]
Proof. Let \( f(x_1, \ldots, x_m) \) be the number of walkers which remained isolated for time \( t \) when for all \( i \in [m] \) the \( i \)-th walker performs the walk \( x_i \). Let \( x := (x_1, \ldots, x_m) \) and let \( x' \) be \( x \) with its \( i \)-th co-ordinate replaced by some other walk \( x'_i \). It is easy to see that \(|f(x) - f(x')| \leq t + 2\). In other words, given the walks performed by the rest of the walkers, the walk performed by the \( i \)-th walker can change the number of walkers which remained isolated for time \( t \) by an additive term whose absolute value is at most \( t + 2 \). Thus (5.1) follows by the McDiarmid’s inequality (3.4).

Let \( A := \{v : \pi_v \leq 2\} \). The second inequality in (5.2) follows by noting that \(|A| \geq |V|/2\) and so \( \pi(A) \geq |A| \min_{v \in V} \pi_v \geq \frac{d}{2|V|} \). We now prove the first inequality in (5.2). As each of the \( m \) walkers w.p. \( \pi \{v : \pi_v \leq 2\} \) has its initial position in \( A \), it suffices to show that for each \( v \in A \) the conditional probability that \( \Pi_v(t) = 1 \) given that the first walker’s initial position is \( v \) is at least \( 2^{-t} \left(1 - \frac{2(t+1)}{|V|}\right)^{m-1} \). Indeed this holds as the probability of the first walker staying put up to time \( t \) is \( 2^{-t} \), while the probability that no other walker visits \( v \) by time \( t \) is

\[
(1 - P_\pi[T_v \leq t])^{m-1} \geq (1 - E_\pi[[i \leq t : X_i = v]])^{m-1} = \left(1 - \frac{2(t+1)}{|V|}\right)^{m-1},
\]

where \( (X_i)_{i \geq 0} \) is a LSRW with \( X_0 \sim \pi \) and \( P_\pi \) and \( E_\pi \) are the corresponding probability and expectation (where we have used \( \pi_v \leq 2/|V| \) since \( v \in A \)).

We now prove (5.3). Let \( X := (X_i)_{i \geq 0} \) and \( (\bar{X}_i)_{i \geq 0} \) be independent LSRWs with \( X_0 \sim \pi \) and \( \bar{X}_0 \sim \pi \). Let \( N(s) := \{|i \leq s : X_i = \bar{X}_i\} \) be the number of times the two walks collide by time \( s \). Since conditioned on the walk that a certain walker performs, the events that each of the other \( m - 1 \) walkers does not collide with it by time \( t \) are independent with the same probability (used in the first equality in (5.4)), by Jensen’s inequality we get that

\[
E^{(m)}[Y(t)] = mE[E[1_{N(t)=0} | X]]^{m-1} \geq mE[E[1_{N(t)=0} | X]]^{m-1} = mP[N(t) = 0]^{m-1}.
\]

Now

\[
P[N(t) \geq 1] \leq \frac{E[N(2t)]}{E[N(2t) | N(t) \geq 1]} \leq \frac{(2t + 1)/|V|}{\min_{v \in V} \sum_{j=0}^{2t} P^{2j}(v,v)},
\]

where we have used regularity to argue that \( \pi \) is the uniform distribution and hence \( E[N(2t)] = \sum_{v \in V} P[X_t = \bar{X}_t] = (2t + 1) \sum_{v \in V} \pi_v^2 = (2t + 1)/|V| \), and reversibility to argue that \( E[N(2t) - N(i - 1) | X_t = \bar{X}_t = v] = \sum_{j=0}^{2t-1} \sum_u P^j(v,u)P^j(v,u) = \sum_{j=0}^{2t-1} P^{2j}(v,v) \), as \( E[N(2t) - N(i - 1) | X_t = \bar{X}_t = v] = \sum_{j=0}^{2t-1} \sum_u P^{j+1}(v,u)P^j(v,u) = P^{2j+1}(v,v) \).

Equations (2.2) and (2.4) follow from the following corollary, in conjunction with the estimate \( P[\text{Pois}(n) \notin [\frac{n}{2}, 2n]] \leq 2e^{-n/16} \), which follows from (3.2).

**Corollary 5.3.** Let \( G = (V, E) \) be a connected \( n \)-vertex Eulerian digraph of average degree \( d \) and minimal degree \( d_{\text{min}} \). Let \( m \in [\frac{n}{2}, 2n] \). Let

\[
\kappa_t := \min_{v \in V} \sum_{i=0}^{t} P^{2i}(v,v) \quad \text{and} \quad s_n := \min \left\{ t : \frac{t+1}{\kappa_{t+1}} > \frac{\alpha}{16} \log n \right\}.
\]

Let \( Y(t) \) be the number of walkers which remained isolated for time \( t \). If \( t \leq \frac{1}{36} \log n \) then

\[
P^{(m)}[Y(t) = 0] \leq \exp \left[ -cn \left( \frac{d_{\text{min}}}{d} \right)^2 e^{-2t} \right].
\]
Rapid social connectivity

In additional, if $G$ is a regular graph then for all $\alpha \in (0,1)$ we have that

$$P^{(n)}[Y(s_\alpha) = 0] \geq \exp\left(-cn^{1-\alpha}(\log n)^{-4}\right). \quad (5.6)$$

Finally, for the usual Poisson setup we have that

$$P[Y(t) = 0] \leq \max_{m \in \mathbb{Z}^+} P^{(m)}[Y(t) = 0] + P\left[\text{Pois}(n) \not\in \left[\frac{n}{2}, 2n\right]\right]. \quad (5.7)$$

Proof. Equation (5.5) follows from (5.1) and (5.2) together with a little algebra. We leave the details as an exercise. Similarly, equation (5.6) follows from (5.1) and (5.3) together with a little algebra, after noting that by Fact 4.8 $s_\alpha \leq s_1 \leq C(\log n)^2$, for all $\alpha \in (0,1]$. Finally (5.7) follows by conditioning on the total number of walkers in the l.h.s. \[ \square \]

Recall the notation from §3 (in particular that $\bar{\pi} := |V|\pi$ that $p((\gamma_0, \cdots, \gamma_t)) := \prod_{i=1}^{t} P(\gamma_{t-i+1}, \gamma_i)$ and that $q(\gamma) := \bar{\pi}\alpha p(\gamma)$ and that $\Gamma_i$ is the collection of all walks of length $t$). The following proposition follows straightforwardly from Fact 3.1 (about Poisson thinning).

**Proposition 5.4.** Let $G = (V,E)$ be a finite connected Eulerian digraph. Let $\gamma = (\gamma_0, \cdots, \gamma_t) \in \Gamma_t$. Then, given that $X_a = 1$, the conditional distribution of the number of walkers that the walker who performed the path $\gamma$ met by time $t$ is Poisson$(a \gamma)$, where

$$a_\gamma := \sum_{\gamma' \in \Gamma_t, \gamma' \neq \gamma, \exists i \gamma_i = \gamma'_i} q(\gamma') \leq -q(\gamma) + \sum_{i=0}^{t} \bar{\pi}_\gamma,$$

In particular,

$$\forall u, \quad P[IL_u(t)] \geq 2^{-t} \bar{\pi}_u e^{-(t+1)\pi_v},$$

$$\forall v \neq u, \quad P[IL_u(t) \cap IL_v(t)] = P[IL_u(t)]P[IL_v(t)]e^{m_{u,v}(t)}, \quad (5.8)$$

where

$$m_{u,v}(t + 1) := \sum_{\gamma \in \Gamma_{t+1}: u, v \in \gamma, \gamma_0 \notin \{v,u\}} q(\gamma) \leq t \bar{\pi}_u P_v[T_u \leq t] + t \bar{\pi}_u P_v[T_v \leq t].$$

Proof: For the inequality, note that the probability that there is one walker at $v$ at time 0 and that this walker is lazy by time $t$ is $\bar{\pi}_v 2^{-t} e^{-\pi_v}$. The conditional probability that no other walker visited $v$ by time $t$ is $P[\text{Pois}(\sum_{\gamma \in \Gamma_t: v \in \gamma, \gamma_0 \neq v} q(\gamma)) = 0] \geq P[\text{Pois}(t \bar{\pi}_v) = 0] \geq e^{-t\pi_v}$.

We now prove the second line of (5.8). Let

$$\Gamma_1 := \{ \gamma \in \Gamma_t: v, u \in \gamma, \gamma_0 \notin \{v,u\}\},$$

$$\Gamma_2 := \{ \gamma \in \Gamma_t: v \in \gamma, u \notin \gamma, \gamma_0 \neq v\} \quad \text{and}$$

$$\Gamma_3 := \{ \gamma \in \Gamma_t: u \in \gamma, v \notin \gamma, \gamma_0 \neq u\}.$$ Denote $b_i := \sum_{\gamma \in \Gamma_i} q(\gamma)$ (where $i = 1, 2, 3$). Then $b_1 = m_{u,v}(t)$ and by the above reasoning

$$P[IL_u(t)] = 2^{-t} \bar{\pi}_u e^{-\pi_v} e^{-(b_1 + b_2)}, \quad P[IL_v(t)] = 2^{-t} \bar{\pi}_v e^{-\pi_u} e^{-(b_1 + b_3)} \quad \text{and}$$

$$P[IL_u(t) \cap IL_v(t)] = (2^{-t} \bar{\pi}_u e^{-\pi_v})(2^{-t} \bar{\pi}_v e^{-\pi_u}) e^{-(b_1 + b_2 + b_3)} = P[IL_u(t)]P[IL_v(t)]e^{b_1}. \quad \square$$
Rapid social connectivity

**Theorem 5.5.** Let $G$ be an $n$-vertex connected graph. Let $\mu := \sum_{v} \pi_v \leq 2\bar{\pi}_v$ (recall that $\bar{\pi} = n\pi$) and $a_t := \mu 2^{-t} e^{-2(t+1)}$. Then for all $t \geq 0$ we have that

$$P[\cup_{k} IL_v(t)] \geq 1 - 7t/\sqrt{a_t}. \quad (5.9)$$

Hence, if there exists some $\delta > 0$ such that $\mu \geq c_1 n^\beta$ for some $\beta > 0$, then for $s_\beta := \max\{[\tilde{c}_\beta \log n - 2 \log \log n] - 1, 0\}$, where $\tilde{c}_\beta := \frac{\beta}{2 \log(2e^2)}$, we have that

$$P[\cup_{k} IL_v(s_\beta)] \geq 1 - 12n^{-\beta/4}. \quad (5.10)$$

**Proof.** We may assume that $7t \leq \sqrt{a_t}$. Let $A := \{v : \bar{\pi}_v \leq 2\}$. Let $\nu_t(x, y) := \sum_{j=1}^{t} P_t^j(x, y)$. Consider $B_a := \{b \in A : \bar{\pi}_a \nu_t(a, b) \geq \bar{\pi}_b/(2\sqrt{a_t})\}$. For every $a \in A$ we have that $\sum_{b \in A} \nu_t(a, b) \leq t$ and so

$$\sum_{b \in B_a} \bar{\pi}_b \leq 2\bar{\pi}_a \sqrt{a_t} \sum_{b \in B_a} \nu_t(a, b) \leq 2\bar{\pi}_a t/\sqrt{a_t}. \quad (5.11)$$

This (together with $7t \leq \sqrt{a_t}$, which implies that $t/\sqrt{a_t} > 1$) implies that there exists some $D \subseteq A$ such that

$$\sum_{a \in D} \bar{\pi}_a \geq \mu/(1 + 2t/\sqrt{a_t}) \geq \mu/(3t/\sqrt{a_t}) \quad (5.12)$$

and

$$\bar{\pi}_a \nu_t(a, b) < \max\{\bar{\pi}_a, \bar{\pi}_b\}/(2\sqrt{a_t}), \quad \text{for all distinct } a, b \in D. \quad (5.13)$$

By (5.8) and (5.10), $E[Z] \geq (a_t/\mu) \sum_{a \in D} \bar{\pi}_a \geq \sqrt{a_t}/(3t)$, where $Z := \sum_{a \in D} Z_a$ and $Z_a := 1_{H_a(t)}$. For all distinct $a, b \in D$, we have that $2\bar{\pi}_a \nu_t(a, b) \leq 4\bar{\pi}_a t/\sqrt{a_t} \leq 4/7$. Thus by (5.11)

$$\exp(2\bar{\pi}_a t P_a[T_b \leq t]) - 1 \leq 4\bar{\pi}_a t P_a[T_b \leq t] \leq 2 \max\{\bar{\pi}_a, \bar{\pi}_b\} t/\sqrt{a_t} \leq 4t/\sqrt{a_t},$$

and so by (5.8)

$$\text{Cov}(Z_a, Z_b)/(E[Z_a]E[Z_b]) \leq \exp(2\bar{\pi}_a t P_a[T_b \leq t]) - 1 \leq 4t/\sqrt{a_t}. \quad (5.14)$$

Hence $L := \sum_{a \neq b, a, b \in D} \text{Cov}(Z_a, Z_b) \leq (E[Z])^2(4t/\sqrt{a_t})$. Finally, since $\text{Var} Z = E[Z] + L$ by Chebyshev’s inequality we have that $P[Z = 0] \leq \frac{\text{Var} Z}{E[Z]^2} \leq \frac{1}{4} + 4t/\sqrt{a_t} \leq 7t/\sqrt{a_t}$. \hfill \Box

The next example demonstrates that the assertion of Theorem 5.5 is quite sharp.

**Example 5.6.** Denote $L_n := \lfloor \log^{10} n \rfloor$. Consider a $[n/L_n]$-clique, such that each vertex in the clique is the center of a star of size $L_n$ (where all stars are disjoint). Then one can show that $SC \leq C \log \log n$ w.h.p. (and if the walkers perform non-lazy SRWs we would get that $SC \leq C$ w.h.p.). The reason for this is that the expected number of walkers whose initial position is not in a center of a star is at most $L_n^2$, while at each vertex of the clique there are Pois($\mu_n$) walkers for some $\mu_n = L_n(1 + o(1))$. An easy calculation shows that w.h.p. after one step all of the walkers whose initial positions are in the clique are in the same class.

**Proof of Theorem 2:** Equation (2.4) follows from Corollary 5.3. We now prove (2.3). Let $G = (V, E)$ be a connected $n$-vertex $d$-regular graph. Consider the SN model on $G$ in which the walks have some fixed holding probability $p \in [0, 1)$. Denote the transition matrix of the corresponding walks by $P$. Recall that $\Gamma_t$ is the collection of all walks on $G$ of length $t$ and that for $\gamma = (\gamma_0, \ldots, \gamma_t) \in \Gamma_t$, $p(\gamma) := \prod_{i=0}^{t-1} P(\gamma_i, \gamma_{i+1})$. Fix
Rapid social connectivity

t = t_n = \lfloor \log n - 6 \log \log n \rfloor - 1. Assume \( t \geq 0 \) as otherwise there is nothing to prove. For every \( \Gamma' \subseteq \Gamma \) let \( m(\Gamma') := \sum_{\gamma \in \Gamma'} p(\gamma) \). For every \( \gamma \in \Gamma \) and \( 0 \leq i \leq t \) let

\[
B_{\gamma,i} := \left\{ v \in V : \sum_{j=0}^{i} p^{[i-j]}(\gamma, v) \geq (t+1)^{-3} \right\},
\]

\( \text{Bad}_i := \{ \gamma \in \Gamma : \exists i \in \{0, 1, \ldots, t\} \text{ such that } \tilde{\gamma}_i \in B_{\gamma,i} \} \).

Clearly \( |B_{\gamma,i}| \leq (t+1)^4 \) for all \( \gamma \in \Gamma \) and \( i \in \{0, 1, \ldots, t\} \), and thus

\[
m(\text{Bad}_i) \leq \sum_{i \leq t} \sum_{v \in B_{\gamma,i}} m(\{ \gamma \in \Gamma : \tilde{\gamma}_i = v \}) \leq \sum_{i \leq t} |B_{\gamma,i}| \leq (t+1)^5. \tag{5.12}
\]

Fix some order \( \prec \) on \( \Gamma \). Recall that \( X_\gamma \) denotes the number of walkers who performed the walk \( \gamma \). We sequentially expose \( X_\gamma \) for some paths \( \gamma \in \Gamma \), according to the following procedure. Assuming that we have already exposed \( A \subseteq \Gamma \) so that the following holds: for every \( \gamma \in A \) with \( X_\gamma > 0 \) we have that \( \text{Bad}_i \cap \{ \gamma' \in A : \gamma < \gamma' \} = \{ \gamma \} \) (where \( \gamma < \gamma' \) indicates that \( \gamma' \) is larger in the ordering than \( \gamma \)). In the next stage we expose \( X_\gamma \) for the minimal \( \gamma' \in \Gamma \setminus B(A) \), where \( B(A) := \cup_{\gamma \in A} X_\gamma \) \( \supseteq \text{Bad}_i \). In the following stage we apply the same rule, with the set \( A \) replaced by the set \( A \cup \{ \gamma' \} \). At the end of this procedure we obtain a collection \( W = \{ \gamma_0^1, \ldots, \gamma_{|W|}^1 \} \) (resp. \( \mathcal{N} \)) of all \( \gamma \)'s for which we exposed that \( X_\gamma > 0 \) (resp. \( \gamma \)). Let \( \mathcal{N}_i \) be the collection of all \( \gamma \in \mathcal{N} \) which were exposed in between \( \gamma_i^{t-1} \) and \( \gamma_i^t \) (and \( \mathcal{N}_i \) is the collection of all \( \gamma \)'s exposed prior to \( \gamma_1^{t} \)). For every \( 1 \leq i \leq |W| \), the probability that \( m(\mathcal{N}_i) > (t+1)^5 \) is at most \( P[\text{Pois}(t+1)^5 = 0] = e^{-(t+1)^5} \). Hence by (5.12)

\[
P(|W| < n/(2(t+1)^5)) \leq ne^{-(t+1)^5} = o(1). \tag{5.13}
\]

We now condition on \( W = W \) and \( \mathcal{N} = \mathcal{N} \) for some arbitrary \( W, \mathcal{N} \subset \Gamma \) so that (i) \( |W| \geq n/[2(t+1)^5] \) and (ii) \( \text{Bad}_i \cap \{ \gamma' \in W : \gamma \prec \gamma' \} = \{ \gamma \} \), for all \( \gamma \in W \). Observe that, given \( (W, \mathcal{N}) = (W, \mathcal{N}) \), the joint distribution of \( (X_\gamma)_\gamma \in \Gamma \setminus (W \cup \mathcal{N}) \) is the same as their unconditional joint distribution. For \( \gamma = (\gamma_0, \ldots, \gamma_t), \gamma = (\gamma_0', \ldots, \gamma_t') \in W \) let

\[
\Gamma_\gamma := \{ \tilde{\gamma} \in \Gamma_\gamma \setminus (W \cup \mathcal{N}) : \exists i \in \{0, 1, \ldots, t\} \text{ such that } \tilde{\gamma}_i = \gamma_i \} \subseteq \text{Bad}_\gamma,
\]

\[
\Gamma_{\gamma,\gamma'} := \{ \tilde{\gamma} \in \Gamma_\gamma : \exists i, j \in \{0, 1, \ldots, t\} \text{ such that } \tilde{\gamma}_i = \gamma_i \text{ and } \tilde{\gamma}_j = \gamma_j' \} \subseteq \text{Bad}_\gamma \cap \text{Bad}_{\gamma'}.
\]

Note that \( m_\gamma := m(\Gamma_\gamma) \leq \sum_{i=0}^{t} m(\{ \tilde{\gamma} \in \Gamma : \tilde{\gamma}_i = \gamma_i \}) = t + 1. \) Denote

\[
D_{i,j}(\gamma, \gamma') := \{ \tilde{\gamma} \in \Gamma : \tilde{\gamma}_i = \gamma_i, \tilde{\gamma}_j = \gamma_j', \forall k < i, \exists k \neq \gamma_k, \forall r < j, \exists r \neq \gamma_r \}
\]

By construction \( \gamma' \notin \text{Bad}_\gamma \), for all \( \gamma, \gamma' \in W \) such that \( \gamma \prec \gamma' \) and so we have that \( \sum_{j=0}^{t} p^{[i-j]}(\gamma, \gamma') < (t+1)^{-3} \) for all \( 0 \leq i \leq t \). Hence by reversibility

\[
m_{\gamma,\gamma'} := m(\Gamma_{\gamma,\gamma'}) = \sum_{0 \leq i < j \leq t} m(D_{i,j}(\gamma, \gamma')) + m(D_{i,j}(\gamma', \gamma)) \leq \sum_{0 \leq i < j \leq t} p^{[i-j]}(\gamma_i, \gamma_j) \leq (t+1)^{-2}.
\]

Finally, for each \( \gamma \in W \) set \( Z_\gamma \) to be the indicator of the event that \( \sum_{\gamma \in \Gamma} X_\gamma = 0 \). Set \( Z = \sum_{\gamma \in W} Z_\gamma \). Observe that (using \( m_\gamma \leq t+1 \) for all \( \gamma \in W \))

\[
E[Z] \geq |W| e^{-(t+1)} > \frac{n}{2(t+1)^5} \left( n^{-1} \log^6 n \right) > \frac{1}{2} \log n
\]

EJP 24 (2019), paper 32. http://www.imstat.org/ejp/
Rapid social connectivity

while similarly to (5.8) for all \( \gamma, \gamma' \in W \) we have that
\[
\text{Cov}(Z_\gamma, Z_{\gamma'})/(\mathbb{E}[Z_\gamma] \mathbb{E}[Z_{\gamma'}]) = e^{\mu_{\gamma+\gamma'}} - 1 \leq e^{1/(t+1)^2} - 1 =: \delta_n.
\]
Hence
\[
\text{Var}(Z) \leq \mathbb{E}[Z] + \delta_n(\mathbb{E}[Z])^2,
\]
which by Chebyshev implies that \( \mathbb{P}[Z = 0] < \frac{1}{\mathbb{E}[Z] + \delta_n}. \)

6 The cycle

In this section we consider the case that \( G \) is the \( n \)-cycle \( C_n \). In this section we assume that at time 0 there is precisely one walker at each site and that the walkers perform independent continuous-time random walks with jump rate 1.

We first prove (2.6). We fix \( s = s_n := C_1 \log^2 n \). By a union bound over the \( n \) edges of the cycle, in order to deduce that \( \mathbb{P}[\text{SC}(C_n) \geq s] \leq C/n \) it suffices to show that for every pair of neighboring vertices \( u, v \), the probability that the walkers who started at those vertices do not have a path of acquaintances by time \( s \) is at most \( C n^{-2} \).

Consider some fixed edge \( e = \{u, v\} \). It partitions the vertices into 2 sides (segments) \( A_u, A_v \) of size roughly \( n/2 \), according to the identity of the end-point to which they are closer to (break a tie arbitrarily). Let \( e' \) be the other edge, apart from \( e \), which connects \( A_u \) and \( A_v \). A walker starting from either \( u \) or \( v \) is extremely unlikely to cross \( e' \) in \( s \) time units.

Let \( \text{CROSS}_s(e, w) \) be the event that the walker who started at vertex \( w \) did not cross \( e' \) by time \( s \) and that her position at time \( s \) is at the opposite side of \( e \) compared to \( w \).

We now argue that for every \( \{w, w'\} \in A_u \times A_v \) the event \( \text{CROSS}_s(e, w) \cap \text{CROSS}_s(e, w') \)
"forces" the walkers who started at \( u \) and \( v \) to have a path of acquaintances by time \( s \) (which uses only walkers whose starting positions are in \( \{u, v, w, w'\} \), possibly a subset of this set). Indeed, the continuous-time setup eliminates the possibility of two walkers swapping positions without meeting. This implies that on the event \( \text{CROSS}_s(e, w) \cap \text{CROSS}_s(e, w') \) it must be the case that by time \( s \) the walkers whose starting positions are \( w \) and \( w' \), resp., have met, and that each of the walkers whose starting positions are \( u \) and \( v \), resp., must have met at least one of the previous pair of walkers (in fact, this is the case for any pair of vertices \( u', v' \) lying in the segment between \( w \) and \( w' \) which contains \( e \)).

This reduces the proof of (2.6) into the following simple calculation: If \( C_1 \) is taken to be sufficiently large then \( \mathbb{P}[\text{CROSS}_s(e, w)] \geq 0.4 \) for every edge \( e = \{u, v\} \) and vertex \( w \) of distance at most \( 10 \log n \) from \( e \). Indeed, starting from such a vertex \( w \), if \( C_1 \) is sufficiently large then the probability of crossing \( e \) by time \( s \) is arbitrarily close to 1/2 (in fact it is arbitrarily close to 1), and for all sufficiently large \( n \) the probability that \( e' \) is crossed by time \( s \) is at most 1/20 (this probability tends to 0 as \( n \) to infinity). Hence (using \( \frac{10}{49} 10 \log n \leq n^{-2} \))
\[
\mathbb{P}[\text{CROSS}_s(e)] \geq 1 - C n^{-2},
\]
where \( \text{CROSS}_s(e) := \bigcup_{w \in A_u, w' \in A_v} \text{CROSS}_s(e, w) \cap \text{CROSS}_s(e, w') \).

This concludes the proof of (2.6). We now prove (2.7). We fix \( t = t_n = c_1 \log^2 n \) for some constant \( c_1 \) to be determined later. Observe that if there are at least 2 edges which no walker crossed by time \( t \), then deterministically \( \text{SC}(C_n) > t \). Let \( \text{NC}_t(e) \) be the event that the edge \( e \in E(C_n) \) was not crossed by any walker by time \( t \). We argue that if \( c_1 \) is taken to be sufficiently small, then for all sufficiently large \( n \) and every edge \( e \) it holds that
\[
\mathbb{P}[\text{NC}_t(e) \mid F] \geq c_3 n^{-1/4}, \quad (6.1)
\]
where $F$ is the event that no walker performed at least $(\sqrt{n}/2) - 2$ steps by time $t$. We now explain how (2.7) can be obtained from (6.1). Denote $m := \lceil \sqrt{n} \rceil$. Let $(e_i)_{i=1}^m$ be a collection of edges which are all at distance at least $\sqrt{n}$ from one another. Then (by a union bound over the $n$ walkers) $1 - P[F] \leq C_2 n e^{-c n^{1/4}} \leq C_2 n e^{-c n^{1/5}}$. Finally, note that conditioned on $F$, the events $(\mathcal{N}_i(e_i))_{i=1}^m$ become independent, and so by (6.1) the conditional probability that none of them occur is at most $(1 - C_2 n^{-1/4})^m \leq e^{-c n^{1/4}}$.

We now prove (6.1). It is not hard to see that in order to prove (6.1) it suffices to show that for every $k$ if we put one particle at each site of $\mathbb{N} := \{1, 2, \ldots\}$ and the particles perform independent continuous-time SRW on $\mathbb{Z}$ with jump rate 1, then the probability that no walker reached the origin by time $k$ is at least $e^{-M \sqrt{k}}$, for some absolute constant $M$. Denote the probability of the previous event by $p_k$. Let $(S'_i)_i \geq 0$ be a SRW on $\mathbb{Z}$ starting at $i \in \mathbb{N}$. Then by the reflection principle (see e.g. [16, §2.7]; the proof in continuous-time is analogous)

\[ a_i(k) := P[ S'_{i} > 0, \forall r \in [0,k] ] = P[ S'_{i} \in \{-i+1, \ldots, i\} ], \quad \text{for all } i \in \mathbb{N}. \tag{6.2} \]

Write $b := [4 \sqrt{k}]$. We argue that there exist constants $c_5, c_6, C_3 > 0$ such that

\[ a_i(k) \geq c_5 i / b, \quad \text{for all } 1 \leq i \leq b. \tag{6.3} \]

\[
\begin{align*}
\quad a_i(k) & \geq 1 - 2 \exp \left( - \frac{\lambda^2}{8k} + \frac{i^4}{4k^3} \right) \geq 1 - 2 \exp \left( - \frac{i^2 \lambda}{8k} \right) \\
& \geq \exp \left( - C_3 e^{-i^2/(8k)} \right), \quad \text{for } b < i \leq 1.2k.
\end{align*} \tag{6.4}
\]

The first line follows from the local CLT. The first inequality in the third line follows from the fact that $1 - a_i(k) \leq P[ \text{Pois}(k) \geq i ]$. The last inequalities in the second and third lines follow from the fact that for every $0 < c < 1$ there exists $C > 0$ such that $1 - x \geq e^{-C x^2}$, for all $x \leq c$ (applied to $x = 2e^{-i^2/(8k)}$ for $i > b$). The first inequality in the second line is obtained by noting that for discrete-time SRW $(\tilde{S}_r)_{r \in \mathbb{Z}}$ starting at the origin we have that $E[e^{\lambda \tilde{S}_r}] = \left( \frac{1}{2} e^\lambda + \frac{1}{2} e^{-\lambda} \right)^r \leq e^{\lambda^2 r/2}$ (by comparing Taylor expansion coefficients). Hence,

\[ E[e^{\lambda S_k}] \leq \sum_r P[ \text{Pois}(r) = r ] e^{\lambda^2 r/2} = \exp[k(e^{\lambda^2/2} - 1)] \leq \exp \left[ k \left( \frac{\lambda^2}{2} + \frac{(\lambda^2/2)^2}{2} \right) \right], \]

as long as $\lambda^2/2 \leq 1$ (using $e^b - 1 \leq b + b^2$ for all $b \in [-1,1]$). We set $\lambda = i/k$, so that indeed $\lambda^2/2 \leq 1$ for $i \leq 1.2k$. Finally, by (6.2), Markov’s inequality and our choice of $\lambda$

\[ 1 - a_i(k) \leq 2e^{L} [S_k \geq i] \leq 2E[e^{\lambda S_k}] e^{-\lambda i} \leq 2 \exp(-i^2/2k) + i^4/(4k^3)]. \]

We are now in a position to conclude the proof. By (6.3) and Stirling’s approximation

\[ \prod_{i \leq b} a_i(k) \geq c_5 b l / b^b \geq \sqrt{b}(c_5/e)^b \geq e^{-C_4 \sqrt{k}}. \]

Denote $b' := \lceil \sqrt{k} \rceil$. Finally, using (6.4) it is not hard to show that

\[ \prod_{i > b} a_i(k) \geq \prod_{\ell > 1.2b'} a_{b'}(k) \cdot \prod_{\ell > 1.2b'} a_{\ell}(k) \geq e^{-C_5 \sqrt{k}} \]

(we leave the details to the reader; Alternatively, since $a_i(k)$ are uniformly bounded away from 0 for $i > b$, we get that $\prod_{i > b} a_i(k) \geq e^{-C \sum_{i > a_i(k)}(1 - a_i(k))}$ and the reasoning in the following remark yields that $\sum_{i > 0} (1 - a_i(k)) = \sum_{i > 0} P[T_0 \leq k] \leq C' \sqrt{k}$). We are done as $p_k := \prod_{i > 0} a_i(k)$. \qed
Rapid social connectivity

Remark 6.1. Consider the usual Poisson setup. The proof of the upper bound on $\text{SC}(C_n)$ is similar to the case of one walker per site at time 0. However, as we now explain, the proof of the lower bound on $\text{SC}(C_n)$ becomes much simpler. While this was already noted in the introduction after Theorem 2, we present below an alternative argument, as it will be used in the analysis of Examples 8.6 and 8.7.

For simplicity, we present the argument in the discrete-time setup. Let $v$ be a vertex in $C_n$. Denote $\nu_t := \sum_{i=0}^{t} P^t(v, v)$ (this sum is independent of $v$). For $t \leq n^2$ we have that $\nu_t = \Theta(\sqrt{t+1})$. By Fact 3.1, the total number of walkers to reach vertex $v$ by time $t$ has a Poisson distribution with mean (by reversibility)

$$
\mu_t := \sum_u P_u[T_v \leq t] = \sum_u \sum_{j=0}^{t} P_u[T_v = j] \leq \frac{1}{\nu_t} \sum_u \sum_{j=0}^{t} P_u[T_v = j] \sum_{i=0}^{2t-j} P^i(v, v)
$$

$$
\leq \frac{C}{\sqrt{t+1}} \sum_u \sum_{i=0}^{2t} P^i(u, v) = \frac{C(2t+1)}{\sqrt{t+1}}.
$$

Thus if $t + 1 < (\frac{\log n}{\Theta(1)})^2$ we get that the probability that no walker reached $v$ by time $t$ is at least $e^{-\mu_t} \geq n^{-1/4}$. This implies the lower bound on $\text{SC}(C_n)$ as in the proof above.

7 Expanders

In this section we study the case that $G$ is a $d$-regular $\lambda$-expander. It is not difficult to extend the results to the case $G$ is an expander of maximal degree $d$. LSRW on a regular $\lambda$-expander $G = (V, E)$ mixes rapidly in the following sense

$$
\max_{x,y \in V} |P^t(x, y) - \pi_y| \leq (1 - \lambda)^t, \quad \text{for all } t.
$$

Indeed $\max_{x \in V} |P^t(x, x) - \pi_x| \leq (1 - \lambda)^t$ follows from the spectral decomposition of $P^t(x, x)$ along with the non-negativity of the eigenvalues of $P$. However, for LSRW on a regular graph $\max_{x,y \in V} |P^t(x, y) - \pi_y| = \max_{x \in V} |P^t(x, x) - \pi_x|$, since in general (cf. [8, (2.2)]) for even $t$ and [16, p. 135] for moving from even $t$ to odd $t$ using laziness

$$
\max_{x,y \in V} |P^t(x, y) - \pi_y| \leq \sqrt{\max_{u,v} \langle \pi_u / \pi_v \rangle \max_x |P^t(x, x) - \pi_x|}.
$$

7.1 Proof of Theorem 4

We argue that Theorem 4 follows from Theorem 5. This follows at once from Corollary 7.2 below. Indeed, after a (“giant”) class of walkers $\mathcal{A}$ of size at least $n/6$ emerges, by Corollary 7.2 (using a union bound over the walkers not in $\mathcal{A}$, together with the concentration of the total number of walkers around $n$), w.p. at least $1 - C_2n^{-1}$, the additional amount of time until every walker not from $\mathcal{A}$ will meet some walker from $\mathcal{A}$ is at most $[C\lambda^{-1} \log n]$.

Lemma 7.1. Let $G$ be a connected $d$-regular $n$-vertex $\lambda$-expander. Then there exists $C > 0$ such that for $t := [C\lambda^{-1} \log n]$ and every $v, u_1, u_2, \ldots, u_t$ sequence of vertices, the probability that a LSRW started at $v$ visits some $u_i$ at time $i$ for some $1 \leq i \leq t$ is at least $\frac{1}{2} \min(\frac{C}{n}, 1)$.

Proof. Let $(X_s)_{s \geq 0}$ be a LSRW on $G$ started at $v$. Let $Y_i = 1_{X_s = u_i}$ and $Y := \sum_{i=1}^{t} Y_i$, where $t := [C\lambda^{-1} \log n]$, for some constant $C$, to be determined shortly. By (7.1), if $C$ is sufficiently large, $E[Y] \geq t/(2n)$, whereas

$$
E[Y | Y_{t+j}] \leq E[Y_i] P^t(u_i, u_{i+j}) \leq E[Y_i](n^{-1} + (1 - \lambda)^j)
$$
and so $E[Y^2] \leq 2E[Y](\lambda^{-1} + t/n)$. Finally,

$$\Pr[Y > 0] \geq \frac{(E[Y])^2}{E[Y^2]} \geq \frac{E[Y]}{2(\gamma^{-1} + \frac{1}{n})} \geq \frac{1}{8} \min \left\{ \frac{\lambda t}{n}, 1 \right\}.$$  \hfill \square

**Corollary 7.2.** Let $G = (V, E)$ be a connected $d$-regular $n$-vertex $\lambda$-expander. Place $\ell := \lfloor n/6 \rfloor$ walkers arbitrarily on $G$ along with one extra walker. Assume all walkers perform independent LSRWs on $G$ simultaneously. Then there exist some constants $C, n_0$, independent of $G, d, \lambda$ and the initial locations of the walks, such that if $n \geq n_0$ the extra walker meets at least one of the other $\ell$ walkers by time $t := \lceil C\lambda^{-1}\log n \rceil$ with probability at least $1 - 1/n^2$ (as usual, meeting means visiting the same vertex at the same time).

**Proof.** First, condition on the walk that the extra walker performed by time $t$, denoted by $\gamma$. Then use Lemma 7.1 and independence to obtain the desired estimate for the conditional probability (uniformly, for all possible values of $\gamma$). Finally, average over $\gamma$.  \hfill \square

### 7.2 Proof of Theorem 5

**Proof:** We adapt a technique from [2, Proposition 3.1] to our setup. Let $t \leq n$ to be determined later. Set $s = s(t, \lambda) := \lceil 8(t + 2)/\lambda \rceil$. Call a class of walkers at time $s$ **good** if the collection of walkers from this class occupy at time $s$ at least $s$ vertices. By Corollary 7.4 below (if $t$ is sufficiently large), w.p. at least $1 - \exp(-c_1 n/d^{\ell t})$ at time $s$ there exists a collection containing at most $n/2t$ good classes such that the walkers belonging to the union of these classes occupy at least $n/2$ vertices at time $s$. We conditioned on this event and on the identity of the good classes from this collection and on the positions at time $s$ of the corresponding walkers. We claim, that if $t$ is taken to be sufficiently large, then w.p. at least $1 - \exp(-c_2 n)$ there is no way of splitting this collection into 2 (disjoint) collections, $A, B$, such that

1. The walkers belonging to the union of the classes in $A$ (resp. $B$) occupy at time $s$ at least $n/6$ vertices.
2. No walker from (the union of the classes in) $A$ met a walker from $B$ by time $s + r$, where $r := \lceil C\lambda^{-1} \rceil$ for some sufficiently large constant $C$.

Indeed, this follows from Lemma 7.5 below which asserts that for any choice of $A, B$ satisfying (i), the probability that (ii) holds is at most $e^{-c_2 n}$, by a union bound over all $\leq 2^{n/2t}$ such partitions (and picking $t$ such that $t \geq \lceil 1/c_2 \rceil$; Recall that in the considered collection of good classes there are at most $n/2t$ classes).  \hfill \square

**Lemma 7.3.** Let $G = (V, E)$ be a connected $d$-regular $n$-vertex $\lambda$-expander. Consider the SN model on $G$. Let $W_u(s)$ denote the walkers who occupy vertex $u$ at time $s$. Write $u \leftrightarrow v$ if there exists a pair of walkers $(w, w') \in W_u(s) \times W_v(s)$ who met each other by time $s$. Let $A_{u,r}(s)$ be the event that $|\{v : u \leftrightarrow v\}| \geq r$. Denote $s := \lceil 8(t + 2)/\lambda \rceil$. Then there exists an absolute constant $c > 0$ such that if $s \leq n$ then

$$\Pr[A_{u,t}(s)] \geq (1 - e^{-1}) - e^{-ct}.$$  

**Proof.** We have that $\Pr[|W_u(s)| > 0] = 1 - e^{-1}$. Throughout the proof we condition on $|W_u(s)| > 0$. Moreover, we fix some walker $w \in W_u(s)$ and condition on the walk $w = (w(0), \ldots, w(s) = u)$ that she performed by time $s$. By averaging, it suffices to show that the conditional probability that $A_{u,t}(s)$ fails is at most $e^{-ct}$ for some constant $c > 0$ independent of $w$. Below, all probabilities and expectations are the conditional ones, given $w$.  

EJP 24 (2019), paper 32.  
http://www.imstat.org/ejp/
Let $(X_k)_{k \geq 0}$ be a LSRW on $G$. We denote the law of $(X_k)_{k \geq 0}$ given $X_0 = v$ by $P_v$. Let $\tau_w := \inf\{k \in [0, s] : X_k = w(s - k)\}$. By Fact 3.1 and reversibility, the (conditional) distribution (given $w$) of the number of walkers not from $\mathcal{W}_v(s)$ that $w$ met by time $s$ has a Poisson distribution with mean $\mu_w := \sum_{v \neq u} P_v[\tau_w \leq s]$. We argue that $\mu_w \geq 4t$. Indeed, let $b_{v,w} := \sum_{i=0}^{s-t} P^i(v, w(s-i))$. By reversibility and (7.1) $\mu_w := \sum_{v \neq u} b_{v,w} = s - b_{v,w} \geq s - \lambda^{-1} - 1$. Again by (7.1) and reversibility, for all $v$

$$b_{v,w} = \sum_{i < s} P_v[\tau_w = i] \sum_{j=0}^{s-i} P^j(w(s-i), w(s-i-j)) \leq \sum_{j=0}^{s-1} \max_{x,y} P^j(x,y) P_v[\tau_w \leq s] \leq P_v[\tau_w \leq s](\lambda^{-1} + 1) \leq 2\lambda^{-1} P_v[\tau_w \leq s].$$

Summing over all $v \in V \setminus \{u\}$ we get that $\mu_w \geq (\lambda/2)\mu_w \geq (\lambda/2)(s - \lambda^{-1} - 1) \geq 4t$, as desired.

Let $Z_v$ be the number of walkers in $\mathcal{W}_v(s)$ who met $w$ by time $s$. Then (conditioned on $w$) $(Z_v)_{v \neq u}$ are independent Poisson random variables such that $E[Z_v] \leq 1$ for all $v$ and $\sum_{v \neq u} E[Z_v] \geq 4t$. Finally, by the (elementary) Lemma 7.6 below we have that $E[|Z_v|] \geq (1 - e^{-t})E[Z_v]$ for all $v$, and so $\sum_{v \neq u} E[|Z_v|] \geq (1 - e^{-t})4t > 2t$. By Bernstein’s inequality (3.3) $P[\sum_{v \neq u} |Z_v| \leq t] \leq e^{-ct}$, for some constant $c > 0$, as desired. □

**Corollary 7.4.** In the setup and notation of Lemma 7.3, there exist $t_0, c_1 > 0$ such that

$$P[\sum_{u \in V} 1_{A_u(s)} < n/2] \leq \exp(-c_1 n/d^{4(s+1)})$$

for all $t \geq t_0$ such that $s = [8(t + 2)/\lambda] \leq n$.

**Proof.** Use Lemma 7.3 together with Azuma inequality on an appropriate Doob’s sequence, by exposing the value of indicators on the l.h.s. sequentially, one at a time. The absolute value of the increments are bounded by the maximal size of a ball of radius $2s$ (which is at most $d^{2(s+1)}$).

□

**Lemma 7.5.** Let $G = (V, E)$ be a connected $d$-regular $n$-vertex $\lambda$-expander. Let $0 < \delta \leq 1/2$. Let $A, B \subset V$ be two disjoint sets of size at least $\delta n$. Put one walker at each vertex of $A \cup B$ and let them perform independent LSRWs. There exists an absolute constant $c > 0$ such that the probability that no walker from $A$ met a walker from $B$ by time $r := \lfloor \lambda^{-1} \log(4/\delta^2) \rfloor$ is at least $\exp[-c \delta^2 n]$.

**Proof.** Let $\mathcal{W}_A, \mathcal{W}_B$ be the collection of walkers occupying $A$ and $B$, respectively, at time 0 (as indicated in the statement of the lemma, at each vertex there is exactly one walker at time 0). Let $D_t$ be the set of vertices which are occupied at time $t$ by at least one walker in $\mathcal{W}_B$. Using Lemma 7.6 below and the fact that $P[u \in D_t] = P^t(u, B) \leq 1$ for all $u$, it is easy to verify that $E[|D_t|] \geq |B|(1 - e^{-t})$ for every $t$. Thus by applying Azuma inequality to an appropriate Doob’s sequence (by exposing the positions at time $t$ of the walkers in $\mathcal{W}_B$ sequentially, one at a time), we get that

$$P[|D_t| < \delta n/4] \leq e^{-c_1 \delta n} \quad (7.2)$$

(the absolute values of the increments of this martingale are bounded by 1). Denote the uniform distribution on $A$ by $\pi_A$ and by $P^r_{\pi_A}$ the distribution at time $r$ of LSRW with $X_0 \sim \pi_A$. If some walker from $\mathcal{W}_A$ is at $D_r$ at time $r$ then this walker meets a walker from $\mathcal{W}_B$ at time $r$. Given that $D_r = D$, the conditional probability that no walker from $\mathcal{W}_A$ is at $D_r$ at time $r$ is at most

$$\prod_{a \in A} (1 - P^r(a, D)) \leq \exp \left[ - \sum_{a \in A} P^r(a, D) \right] = \exp \left[ - |A| P^r_{\pi_A}(D) \right].$$
Rapid social connectivity

To conclude the proof, we show that $\Pr_{\pi_A}^r(D) \geq \delta/8$ for all $D \subseteq V$ such that $|D| \geq \delta n/4$, which implies the assertion of the Lemma using (7.2).

Let $\pi$ be the uniform distribution on $V$. Recall that for every $\rho \geq 1$ the $\ell_\rho$ distance between a pair $\mu, \nu$ of distributions on $V$ is defined as $\|\mu - \nu\|_{\rho, \pi} := \left[ \sum_{v \in V} \pi(v) (\frac{\mu(v) - \nu(v)}{\pi(v)})^\rho \right]^{1/\rho}$ and $\|\mu - \nu\|_{\infty, \pi} := \max_{v \in V} |\mu(v) - \nu(v)|$. Then

$$\|\pi_A - \pi\|_{2, \pi} \leq \|\pi_A - \pi\|_{\infty, \pi} \leq n/|A|.$$ 

By Jensen’s inequality (first inequality below) and the Poincaré inequality (second inequality below) satisfied by the spectral gap (cf. [1, Lemma 3.26])

$$\|\Pr_{\pi_A}^r - \pi\|_{1, \pi} \leq \|\Pr_{\pi_A}^r - \pi\|_{2, \pi} \leq (1 - \lambda)^r \|\pi_A - \pi\|_{2, \pi} \leq n/|A| e^{-\lambda r} \leq \delta/4,$$

where the last inequality follows from the choice of $r$. As

$$\|\Pr_{\pi_A}^r - \pi\|_{1, \pi} = \sum_{v} |\Pr_{\pi_A}^r(v) - \pi(v)| = 2 \left( \max_{D \subseteq V} \pi(D) - \Pr_{\pi_A}^r(D) \right),$$

it follows that if $|D| \geq \delta n/4$ then

$$\Pr_{\pi_A}^r(D) \geq \pi(D) - \frac{1}{2}\|\Pr_{\pi_A}^r - \pi\|_{1, \pi} = |D|/n - \delta/8 \geq \delta/8.$$

\begin{lemma}
For all $x \in [0,1]$, $(1 - e^{-x}) \geq (1 - e^{-1})x$. In particular, for all $x \in [0,1]$, if $Y \sim \text{Pois}(x)$ or $Y = \sum_{i=1}^m \xi_i$, where $\xi_1, \ldots, \xi_m$ are independent Bernoulli r.v.’s with $\sum_{i=1}^m E[\xi_i] = x$, then (by Lemma 4.13) $P[Y \geq 1] \geq 1 - e^{-E[Y]} \geq (1 - e^{-1})E[Y]$.
\end{lemma}

8 Concluding remarks, conjectures and open problems

8.1 Allowing different communities of walkers

It is not hard to see that the proof of (2.1) can also be extended to the following setup in which there are $m$ “communities” of walkers. Let $m \leq n$. Let $k_1, \ldots, k_m > 0$ be such that $\sum_{i=1}^m k_i = n$. Let $G_1, \ldots, G_m$ be connected graphs on the same vertex set $V$ of size $n$. Denote the stationary distribution of LSRW on $G_i$ by $\pi^i$. At time $0$ there are $\text{Pois}(k_i \pi^i_v)$ walkers at vertex $v$ performing independent LSRWs on $G_i$ (for all $1 \leq i \leq m$ and $v \in V$, independently). As usual, when two walkers reach the same vertex at the same time they become acquainted, even if they walk on different graphs. The bound on SC depends in this case on $\max_{i} d^{(i)}$, where $d^{(i)}$ is the average degree of $G_i$.

8.2 Dependence on the maximal degree and the vertex-transitive setup

\begin{definition}
We say that a bijection $\varphi : V \rightarrow V$ is an automorphism of a graph $G = (V, E)$ if $(u, v) \in E \iff (\varphi(u), \varphi(v)) \in E$. A graph $G$ is said to be vertex-transitive if the action of its automorphisms group $\text{Aut}(G)$ on its vertices is transitive (i.e. $\{\varphi(v) : \varphi \in \text{Aut}(G)\} = V$ for all $v$).
\end{definition}

\begin{conjecture}
There exists some $C > 0$ such that for every connected $n$-vertex graph $G$ of average degree $d$, with probability at least $1 - C/n$ we have that

$$\frac{SC(G)}{(\log n)^2} \leq C(d^2 1_G \text{ is non-regular} + d 1_G \text{ is regular but not vertex-transitive} + 1)$$

\end{conjecture}

\begin{conjecture}[Monotonicity in the number of walkers]
Denote by $SC(G, k)$ the social connectivity time when we have $k$ walkers, each starting at a vertex chosen from the stationary distribution $\pi$ independently of the rest of the walkers. Then for every vertex-transitive graph $G$ we have that $E[SC(G, k)]$ is monotonically non-increasing in $k$ for $k \geq 2$.
\end{conjecture}
Rapid social connectivity

**Open Problem 8.4.** Let $G = (V, E)$ be a finite connected vertex-transitive graph. Let $o \in V$. Consider the SN model on $G$. Consider

- $t(G)$ - the minimal integer satisfying $t(G) \geq \log |V| \sum_{i=0}^{t(G)} P^i(o, o)$,
- $\tau_1$ - the minimal time in which all classes are of size at least 2,
- and $\tau_2$ - the minimal time by which every vertex has been visited by at least one walker.

Is there an absolute constant $C$ such that

$$\max\{E[SC(G)], E[\tau_1], E[\tau_2], t(G)\} \leq C \min\{E[SC(G)], E[\tau_1], E[\tau_2], t(G)\}?$$

**Conjecture 8.5.** Consider a sequence $G_n$ of vertex-transitive graphs of increasing sizes. Then in the notation of Open problem 8.4,

$$SC(G_n)/E[SC(G_n)] \to 1 \quad \text{and} \quad \tau_i(G_n)/E[\tau_i(G_n)] \to 1 \quad (i = 1, 2) \quad \text{in distribution, as } n \to \infty.$$

We believe that in the setup of the previous conjecture it is often the case that $[SC(G_n) - \tau_1(G_n)]/E[SC(G_n)] \to 0$ in distribution (e.g. we believe this is the case for transitive expanders). However, this might not be the case for the $n$-cycle. It is plausible that Conjecture 8.5 holds even without the transitivity assumption as long as the graphs $G_n$ are of bounded degree. Conversely, if $G_n$ is two disjoint $n$-cliques connected by an edge, then $E[SC(G_n)]$ converges in distribution to the Exponential distribution with parameter 1.

In the last example we have that $E[SC(G_n)] = \Theta(n)$. This shows $E[SC(G_n)]$ may increase with the maximal degree. Below are two families of graphs, generalizing the previous example, which we believe to be extremal.

**Example 8.6.** In general, $E[SC(G)]$ may grow linearly in $d$, even when $G$ is regular, as the following example demonstrates. Consider two disjoint $n$-cliques. Delete an edge from each clique and connected the two cliques by two edges so that the obtained graph is $(n-1)$-regular. By considering the time required until some walker visits both cliques it is not hard to show that $E[SC] \geq cn$. We now describe a similar construction of $d$-regular graphs which satisfy $E[SC] \geq cd \log^2(n/d)$.

Fix some $2 \leq d \leq n$ such that $2d \leq n$. Let $J_d$ be a graph obtained from the complete graph on $k$ vertices by deleting a single edge. Consider $[n/d]$ disjoint copies of $J_d$: $I_0, \ldots, I_{n/d}-1$, where for all $0 \leq j < [n/d]$, $I_j$ is connected to $I_{j+1}$ ($j+1$ is defined mod $[n/d]$) by a single edge that connects two degree $d-1$ vertices. This can be done so that the obtained graph is $d$-regular. It is not hard to verify that the obtained graph satisfies $E[SC] \geq cd \log^2(n/d)$.

To see this, observe that similarly to the analysis of the $n$-cycle it suffices to show that provided that $c$ from the definition of $s$ is taken to be sufficiently small, with probability bounded from below (in fact, w.h.p. SC $\geq s$). To see this, observe that similarly to the analysis of the $n$-cycle it suffices to show that provided that $c$ from the definition of $s$ is taken to be sufficiently small, with probability bounded from below (in fact, w.h.p. when $d \ll n$ there will be multiples $j$’s such that no walker crossed the edge connecting $I_j$ with $I_{j+1}$ by time $s$. To prove this, one can imitate the analysis from Remark 6.1. The claimed bound becomes intuitive when one considers the fact that the projection of the walk to the index of the copy of $J_d$ to which it belongs, behaves similarly to a random walk on the $[n/d]$ cycle with holding probability $1 - 1/j_d^2$. Thus the expected number of walkers to cross an edge connecting two copies of $J_d$ by time $s$ is comparable to $d$ times the expected number of walkers which cross a certain edge by time $s/d$ for the $n$-cycle (one has to multiply by $d$ as $J_d$ has $d$ vertices).

We now consider a non-regular family of examples.

**Example 8.7.** Consider two disjoint $n$-cliques connected by a path of length $n$. Using the fact that the number of walkers which initially occupy the $n$-path has a Poisson distribution with a constant mean, it is not hard to show that $E[SC] \geq cn^2$. 

EJP 24 (2019), paper 32. http://www.imstat.org/ejp/
Rapid social connectivity

We now describe a similar construction whose maximal degree is $d \leq 8|V|$ which satisfy $E[|C|] \geq c|d \log(|V|/d)|^2$. Take $[n/d]$ copies of $J_d$: $I_0, \ldots, I_{[n/d]-1}$ and for all $0 \leq k < [n/d] - 1$ connect $I_k$ to $I_{k+1}$ via a path of length $d$.

To see that $E[|C|] \geq c|d \log(n/d)|^2 = t_{d,n}$, observe that with positive probability (in fact, w.h.p. if $d \ll n$) there will be many vertices lying in the middle of a length $d$ path (connecting some $I_k$ to $I_{k+1}$) which will not be visited by a single walker up to time $t_{d,n}$. We leave the details to the reader (hint: use the idea from Remark 6.1).

8.3 Additional Open Problems

The following conjecture concerns the existence of infinite classes of walkers after a constant number of steps in the setup of infinite graphs.

**Conjecture 8.8.** Let $G$ be a connected infinite bounded degree graph such that the critical density for independent percolation on $G$ is strictly less than 1. If the number of walkers at time 0 at each vertex $v$ has a Pois$(\lambda v)$ distribution, independently for different $v$’s (let $P_\lambda$ be the corresponding probability measure), then for every $\lambda > 0$ there exists $t_c(\lambda, G) > 0$ such that for all $t > t_c(\lambda, G)$,

$$P_\lambda[\text{there exists an infinite class of walkers at time } t] = 1.$$

Let $K_n$ be the complete graph on $n$ vertices. When the holding probabilities of the walks are taken to be either $q_v = 0$ or $q_v = 1/n$, one can show that after a single step the SN model (with Pois(1) walkers per site) behaves in some sense like a critical Erdős Rényi random graph, $G(n, 1/n)$, while after two steps it behaves like the super-critical random graph $G(n, 2/n)$ (hence w.h.p. a giant class of walkers emerges after precisely 2 steps). We believe that also in the continuous-time setup there is a phase transition.

**Open Problem 8.9.** Consider the SN model on $K_n$ in continuous-time (each walker has jump rate 1). What is the critical time $t_c$ for the emergence of a giant class of walkers?

A Deferred proofs

A.1 Proof of Lemma 4.10

**Lemma 4.10** Let $\xi_1, \ldots, \xi_m$ be independent Poisson random variables. Let $p_1, \ldots, p_m \in (0, 1)$. Denote $p_* := \max p_i$, $S := \sum_{i=1}^m p_i \xi_i$ and $\mu := E[S]$. Then for all $\varepsilon \in (0, 1]$

$$P[S \leq (1-\varepsilon)\mu] \leq e^{-\frac{1}{2}\mu\varepsilon^2/p_*}.$$  

$$P[S \geq (1+\varepsilon)\mu] \leq e^{-\frac{1}{2}\mu\varepsilon^2/p_*}.$$  

**Proof:** Denote $\mu_i := E[\xi_i]$ and $\lambda := \varepsilon/p_*$. As $\sum_k e^{-\lambda p_i k} \mu_i^k / k! = e^{\mu_i e^{-\lambda p_i}}$ and $\lambda p_i \leq 1$ (which implies that $e^{-\lambda p_i} - 1 \leq -\lambda p_i + \frac{1}{2}(\lambda p_i)^2$) we have that

$$E[e^{-\lambda p_i \xi_i}] = \exp[\mu_i(e^{-\lambda p_i} - 1)] \leq \exp[\mu_i(-\lambda p_i + \frac{1}{2}(\lambda p_i)^2)] \leq \exp[\mu_i(-\lambda p_i + \frac{1}{2}(\lambda p_i)^2)]$$

Finally, by Markov’s inequality and the choice of $\lambda$

$$P[S \leq (1-\varepsilon)\mu] = P[e^{-\lambda S} \geq e^{-\lambda(1-\varepsilon)\mu}] \leq E[e^{-\lambda S}] e^{-\lambda S(1-\varepsilon)\mu} \leq \exp[\mu_i(-\lambda p_i + \frac{1}{2}(\lambda p_i)^2)]$$

Similarly, let $a := \varepsilon/(2p_*)$. Then $\sum_k e^{ap_i k} \mu_i^k / k! = e^{\mu_i e^{ap_i}}$. Since $ap_i \leq 1$ we have that $e^{ap_i} - 1 \leq ap_i + (ap_i)^2$ and so

$$E[e^{ap_i \xi_i}] = \exp[\mu_i(e^{ap_i} - 1)] \leq \exp[\mu_i(ap_i + (ap_i)^2)] \leq \exp[\mu_i(ap_i + a^2 p_i)]$$

EJP 24 (2019), paper 32.

Rapid social connectivity

\[ \mathbb{E}[e^{aS}] = \prod_{i=1}^{m} \mathbb{E}[e^{a\mu_i}] \leq \exp[\sum_{i=1}^{m} \mu_i(a + \lambda^2 p_i)] = \exp[\mu(a + \lambda^2 p_i)]. \]

Finally, by Markov’s inequality and the choice of \( a \) we get that

\[ P[S \geq (1 + \epsilon)\mu] = P[e^{aS} \geq e^{a(1+\epsilon)\mu}] \leq \mathbb{E}[e^{aS}]e^{a(1+\epsilon)\mu} \leq e^{\mu(a+\lambda^2 p_i)} = e^{-\mu^2/(4p_i)}. \]

A.2 Proof of Lemma 4.2

**Lemma 4.2** Let \( J_k \) be a non-increasing \( \mathbb{Z}_+ \)-valued random process, measurable w.r.t. filtration \((\mathcal{F}_k)_{k \geq 0}\), with \( J_0 \leq m \), satisfying that for some \( 0 < \alpha, p, \varepsilon_m < 1 \), for each \( k \) there exists some events \( A_k \in \mathcal{F}_k \) with \( P(A_k) \geq 1 - \varepsilon_m \) satisfying that

\[ E[1_{\{J_{k+1} \leq (1-p/2)J_k\}}1_{A_k} | \mathcal{F}_k] \geq \alpha 1_{A_k}. \]

**Proof:** Let \( T_0 := \inf\{k : J_k = 0\} \). Then there exists some constant \( C_{\alpha,p} \leq K/(\alpha p) \) such that

\[ P[T_0 > |C_{\alpha,p} \log m|] \leq m^{-2} + \varepsilon_m(\{C_{\alpha,p} \log m\} + 1). \]

\[ P[T_0' \geq L] \leq m^{-2} \]

(since \( P[T_0' \geq L] - P[T_0 \geq L] \leq P(\{L_{m-1} \geq B_h\}) \)).

A.3 Proof of Lemma 4.14

**Lemma 4.14** Let \( G = (V, E) \) be a finite Eulerian graph. Let \( Y_v(t) \) be the number of walks which occupy vertex \( v \) at time \( t \), where \((Y_v(0))_{v \in V}\) is some arbitrary deterministic initial configuration of walkers and different walkers perform independent LSRWs. Let \((v, u) \in E\). Let \( Y := \max_{x \in V} \frac{\sum}{\sum} Y_x(0) \). Then

\[ 2d_{v,u}E[Y_v(t)] \geq E[Y_v(t-1)] \geq \frac{1}{3}(E[Y_v(t)] - Y \exp(-c_1 t)). \]  

\[ (A.1) \]

**Proof:** The first inequality in (A.1) is trivial. We now prove the second inequality. Let \( v \in V \) and \( t \in \mathbb{N} \). We say that a path \( \gamma' \) is non-lazy if \( \gamma'(i) \neq \gamma'(i+1) \) for all \( i \). Let \( \Gamma_{t} \) be the collection of all non-lazy paths of length at most \( \ell \) which terminate at \( v \). For a walk \( \gamma \) let \( \gamma' \) be its projection to its non-lazy version (obtained by omitting from \( \gamma \) coordinates with the same value as that of the previous time unit).

For every \( \gamma' \in \Gamma_{t} \) (resp. \( \gamma' \in \Gamma_{t-1} \)) let \( W_{\gamma'}(t) \) (resp. \( W_{\gamma'}(t-1) \)) be the collection of walks of length \( t \) (resp. \( t-1 \)) whose non-lazy version is \( \gamma' \). Let \( \bar{P} \) be the transition matrix of the non-lazy walk (i.e. \( \bar{P} = \frac{1}{2}(I + \bar{P}) \), where \( I \) is the identity matrix). Let \( b_k := P[\text{Bin}(t, \frac{1}{2}) = k] \) and \( a_k := P[\text{Bin}(t, \frac{1}{2}) > k] \). We first note that the contribution to \( E[Y_v(t)] \) coming from walks in \( \cup_{\gamma'} \mathcal{F}_{t} \setminus \mathcal{U}_{\gamma'} \) \( W_{\gamma'}(t) \) (i.e. from walks \( \gamma' \)’s with less than \( t/3 \) lazy steps) is at most

\[ \sum_{k > 2t/3} b_k \sum_{x} Y_x(0) \bar{P}^{k}(x,v) \leq \sum_{k > 2t/3} b_k \sum_{x} Y_x \frac{Y}{d_x} \sum_{x} d_x \bar{P}^{k}(x,v) = a_{2t/3}Y \leq Y e^{-c_1 t}. \]  

\[ (A.2) \]
Rapid social connectivity

where we have used \( \sum_{k>2t/3} b_k \leq e^{-c_1 t} \), and \( \pi \hat{p}^k = \pi \) to argue that \( \sum_x d_x \hat{p}^k(x,v) = d_v \).

Recall (§3) that \( p(\gamma) \) is the probability that a walker starting from \( \gamma \) performs the walk \( \gamma \). Let \( \gamma' \in \Gamma_{\hat{\gamma}} \). We argue that the total contribution to \( E[Y_{\gamma'}(t)] \) coming from walks in \( W_{\gamma'}(t) \) (which equals \( \sum_{\gamma \in \Gamma_{\gamma'}} p(\gamma) Y_{\gamma(0)}(0) \)) is larger than the contribution to \( E[Y_{\gamma}(t - 1)] \) coming from walks in \( W_{\gamma}(t - 1) \) (which equals \( \sum_{\gamma \in \Gamma_{\gamma}} p(\gamma) Y_{\gamma(0)}(0) \)) by a factor of at most 3. Since the total number of lazy steps performed is at least \( t/3 \), the “cost” \( \sum_{\gamma \in \Gamma_{\gamma}} p(\gamma) \)\( Y_{\gamma(0)}(0) \) of making one less lazy step is bounded from above by

\[
\sup_{k \in \mathbb{N}: k \geq t/3} \frac{\left( \frac{t}{k} \right)}{\left( \frac{t}{k} - 1 \right)} = \sup_{k \in [t/3,t]} \frac{t - k + 1}{k} \leq 3.
\]

Putting everything together gives:

\[
E[Y_{\gamma'}(t - 1)] \geq \sum_{\gamma' \in \Gamma_{2t/3}} \sum_{\gamma \in \Gamma_{\gamma'}} p(\gamma) Y_{\gamma(0)}(0) \geq \frac{1}{3} \sum_{\gamma' \in \Gamma_{2t/3}} \sum_{\gamma \in W_{\gamma'}} p(\gamma) Y_{\gamma(0)}(0).
\]

By (A.2) the rightmost term above is at least \( \frac{1}{3} \left( E[Y_{\gamma'}(t)] - 2 \exp(-c_1 t) \right) \), as desired. \( \square \)

Advantages of publishing in EJP-ECP

- Very high standards
- Free for authors, free for readers
- Quick publication (no backlog)
- Secure publication (LOCKSS\textsuperscript{1})
- Easy interface (EJMS\textsuperscript{2})

Economical model of EJP-ECP

- Non profit, sponsored by IMS\textsuperscript{3}, BS\textsuperscript{4}, ProjectEuclid\textsuperscript{5}
- Purely electronic

Help keep the journal free and vigorous

- Donate to the IMS open access fund\textsuperscript{6} (click here to donate!)
- Submit your best articles to EJP-ECP
- Choose EJP-ECP over for-profit journals
