ABSTRACT

Objective: To determine the variations in peak growth hormone levels during insulin tolerance test (ITT) in diagnosis of growth hormone deficiency (GHD) in children presenting with short stature.

Study Design: Descriptive study.

Place and Duration of Study: Department of Pediatric Endocrinology, National Institute of Child Health (NICH), from January to December 2018.

Methodology: Clinical records of all children who underwent ITT during the above mentioned period were reviewed. All 348 children of either gender from 2-17 years of age with height more than 2SD below the mean (<3rd percentile) suspected GHD and subjected for ITT were included. Verbal consent was taken from all parents. Children below 2 years and with other causes of Short Stature like hypothyroid, celiac, cardiac, chronic liver, kidney diseases and syndrome were excluded.

Results: Total 348 children were subjected to ITT. Out of these 48.3% were found to have GH levels <5ng/ml, 33.6% b/w 5-10 ng/ml and 18.1% >10 ng/ml. Precisely peak GH levels at different time intervals are 1.1%, 19.3%, 47.4%, 29.9%, and 2.3% for 0, 30, 60, 90 and 120 minutes respectively. Mostly peak growth hormone levels were accomplished at 60 minutes followed by 90 and then at 30 minutes. Hypoglycemia was achieved 0.8%, 47%, 26%, 24% and 1% at 0, 30, 60, 90, and 120 minutes.

Conclusion: The 0, 30, 60, and 90 minutes samples are adequate to confirm the diagnosis of GH deficiency. This shorter duration of ITT to 90 minutes is cost effective as it decreases the financial burden of unnecessary testing. Additionally, it reduces the risk of side effect like hypoglycemia.

Key Words: Short stature, Growth hormone deficiency, Insulin tolerance test.

INTRODUCTION

A pediatric patient with short stature and no clinically apparent explanation needs to be referred to pediatric endocrine clinic to identify the cause. After exclusion of other clinical conditions, which may lead to short stature, a subsequent diagnosis of growth hormone deficiency (GHD) may be made in which GH therapy has been approved.1,2 GH is essential in children for their normal growth and metabolism. Without enough GH, a child grows slowly; and remains much shorter than other children of the same age and gender.3 The consequent delay in making the diagnosis can undermine the efficacy of GH treatment, so the appropriate diagnosis should be made and treatment be started as soon as possible.2

Short stature is defined as the height below 0.4th centile of 1990 Growth Reference Chart or a height more than 2 standard deviation below the mean for that age and gender (which corresponds to a height below the 2.3rd percentile).5 In the assessment of GHD, child’s medical history and growth charts should be reviewed. Furthermore, both clinical and auxological data are required to know the cause of slow growth.6 In addition to auxological parameters, biochemical investigations are also mandatory, such as complete blood count, liver function test, renal biochemistry, and tissue transglutaminase to rule out other causes of reduced growth. To facilitate the diagnosis of GHD, GH stimulation test is performed where the child is given provocative agent to release growth hormone from the pituitary gland. If certain blood level of GH is not achieved after stimulation, it means the pituitary is not making enough GH. Along with GH stimulation test, insulin growth factor-1(IGF-1, a hormone that reflects GH levels) and insulin like growth factor binding protein 3 (IGFBP3, a binding protein that binds with IGF-1 with very high affinity) are also important. Moreover, X-ray wrist for the child’s bone age, and MRI pituitary to rule out pituitary hypoplasia or other pituitary disorders are also included.2

Different provocative agents like insulin, arginine, clonidine, glucagon, and GH releasing hormone (GHRH) are used as potent stimulator of GH secretion for the diagnosis of growth hormone deficiency. Due to the pulsatile nature of GH secretion, a single blood sample of GH measurement is not informative. Arginine and clonidine are not available in Pakistan and L-Dopa is not routinely performed for the diagnosis of GHD in children. Insulin tolerance test (ITT) is an important tests, and having good diagnostic yield; but can lead to serious complications, if not performed correctly. The recommended time duration of ITT is 120 minutes.

The aim of this study was to ascertain the variations in peak growth hormone levels during insulin tolerance test for short stature; whether it is with shorter time period, i.e. less than 120 minutes and cost-effective analysis.

**METHODOLOGY**

After Ethical Review Board approval, this retrospective study was conducted at the Pediatric Endocrinology Department, National Institute of Child Health, Karachi. Clinical data of children, subjected for ITT from January to December 2018, has been reviewed from the record files. All children aged 2-17 years of either gender, who visited the Pediatric Endocrine Clinic, with complain of short stature having height more than 2.5 SD below the mean (< 3rd percentile), were included. In children above 12 years, priming was done by single injection of testosterone intramuscular 25mg depot, 7-10 days before GH testing in boys; and 1.25 mg oral conjugated estrogen for 3 days before testing, in girls. Those children who were less than two years, untreated or inadequately treated hypothyroidism, celiac disease, cardiac disease, chronic liver disease, renal problems and syndromes, were excluded. All selected patients underwent insulin tolerance test (ITT). After taking consent from parents, ITT was performed in the presence of trained staff under strict precautions. Insulin was given 0.1 unit/kg subcutaneously and blood samples were drawn for serum blood glucose and serum growth hormone at 0, 30, 60, 90, and 120 mins after giving insulin. We also checked all the blood glucose levels on glucometer during ITT for hypoglycemia. In these time intervals, the blood sugar level <50 mg/dl or 2/3rd of highest blood sugar level achieved, was considered as hypoglycemia. The cut-off level of GH <10 ng / ml was considered as the gold standard for growth hormone deficiency. Growth hormone level <5 ng/ml was considered to be severe GH deficiency; 5-10 ng/ml was moderate GH deficiency, and above 10 ng/dl was considered normal.

The samples of serum blood glucose were analysed by analyser on Dimension RxL and serum growth hormone by ELISA on immulite 1000 at the laboratory of National Institute of Child Health.

Mean and standard deviation values of age and height measurements were calculated. Frequencies and percentages of qualitative variable like gender were also measured. SPSS version 18 was used for statistical analysis.

**RESULT**

A total of 348 children between the ages of 2-17 were subjected to ITT. There were 200 (57.5%) females and 148 (42.5%) males. The mean age of the subjects was 10.34 ± 3.37 years and mean height was 117.4 ± 14.53 cm. Half of the children aged 8-12 years; while in the remaining half, 22% of children were the ages of 2-7 years and 28% were of 13-17 years, respectively. Children are closely monitored for their blood sugar levels at fixed time intervals. Maximum number of the children (47.1%) developed hypoglycemia at 30 minutes of commencement of the test; and the percentage of children developing hypoglycemia decreased in subsequent readings at 60, 90 and 120 minutes (Figure 1). Similarly, around 50% of the children reached peak GH level at 60 minutes; whereas, 30% and 20% reached the peak GH level at 90 and 30 minutes, respectively. Only 2% children achieved peak GH levels at 120 minutes (Table I).

**Table I: Frequency of hypoglycemia and peak GH levels at 0, 30, 60, 90, and 120 minutes.**

| Time Interval | No of children with blood sugar <50 mg/dl or 2/3rd of highest blood sugar level | No of children with peak GH levels after administration of insulin |
|---------------|---------------------------------------------------------------------------------|------------------------------------------------------------------|
| 0 minutes     | 3 (0.9%)                                                                         | 4 (1.1%)                                                         |
| 30 minutes    | 164 (47.1%)                                                                      | 67 (19.3%)                                                       |
| 60 minutes    | 93 (26.7%)                                                                       | 165 (47.4%)                                                      |
| 90 minutes    | 84 (24.1%)                                                                       | 104 (29.9%)                                                      |
| 120 minutes   | 4 (1.1%)                                                                         | 8 (2.3%)                                                         |
There was a significant difference between blood sugar and peak growth hormone levels at 30, 60 and 90 minutes, which were recorded. The peak GH levels at 120 minute interval were markedly reduced (Figure 2).

In the study group of 348 children, 168 (48.3%) were diagnosed with severe GHD having GH levels <5ng/ml, 117 (33.6%) with moderate GHD having GH levels b/w 5-10 ng/ml and 63 (18.1%) with normal GH levels >10 ng/ml.

**DISCUSSION**

Short stature is a common reason for referral to pediatrics endocrine clinics. Classically, short stature is divided into idiopathic short stature (ISS) without any noticeable causes and into the children with growth hormone deficiency (GHD). Recently, ISS is further subdivided into familial short stature (FSS) and non-familial short stature (NFSS) which also includes short children with constitutional delay of growth and puberty.10,11

The prevalence of GHD in children is approximately 1 in 4000.12 Although GHD is uncommon, it is crucial to diagnose it correctly and as early as possible, as a missed or late diagnosis can impede GH therapy and lead to poor outcomes.12 The diagnosis is currently based on clinical assessments like short height, slow growth velocity and needs supporting evidences from radiological and biochemical investigations.12,13

To establish the diagnosis of GHD, the assessment of peak GH levels remains challenging, as random serum GH concentration has no clinical value due to its pulsatile nature. When the first GHD stimulation test used in 1960s, a peak GH concentration of <5 ng/ml (ug/l) was used to diagnose GHD. Over the years, this cut-off value has raised to 7 ng/ml (ug/l) and then 10 ng/ml (ug/l) due to insufficient validation of clinical studies.13,14

Different stimulation tests have been used to establish the diagnosis of GHD. Insulin tolerance test was first used as GH secretion test; later, different pharmacological agent shave been used like glucagon, clonidine, arginine, levodopa and GHRH. The diagnosis of GHD, which obligates GH replacement therapy, is established with peak GH serum concentration below the cut-off value by at least two GH stimulation tests.15 In one study, done in South Korea, GHD was considered as a serum peak GH concentration <10 ng/ml on provocation with the combination of two separate provocative tests.15 Arginine and clonidine are not available in Pakistan, and L-Dopa is not routinely performed for the diagnosis of GHD in children.

Insulin-induced hypoglycemia, being the commonest test, is used in GH secretion; but the mismanagement of hypoglycemia may lead to serious complications. Initially, early in 1992, two children who died and one suffered from neurological damage after performance of GH secretion test were reported.16 Later, a number of studies have been done to explain the safety and accuracy of ITT in pediatric settings.16 However, this test is potentially dangerous and necessitates a prolong time duration in a pertinent equipped investigation unit, which makes it very expensive and unsuitable for the screening purpose outside specialised clinic.17

Multiple studies have also been done to see the diagnostic efficacy of growth hormone samples at different time intervals. This is because severe hypoglycemia is one of the potentially dangerous side effects of ITT. In one study, conducted in Thailand, the lowest level of blood sugar was achieved within 45 minutes and peak growth hormone level recorded within 90 minutes of insulin administration. So, they concluded that secure and persuasive ITT can be performed with lesser samples in short span of time.18 In another published local study, ITT observed a cost effectiveness of 29%, if the 120 minutes sample is omitted.7,19 Similar result is found in this analysis, in which 47.4% patients achieved peak growth hormone levels at 60 minutes, followed by 29.9% at 90 minutes, and 19.3% at 30 minutes. It will be 24% cost-effective, if the 120 minutes sample is omitted. These results will be very helpful and beneficial in reducing costs and sampling numbers in a very expensive test, especially in developing countries.

ITT is, therefore, can be performed with lesser samples in shorter period of time in a centre fully equipped and with experienced staff. In the present study, the authors used single ITT because of the financial cost. It is suggested that the study should be conducted on larger scale with two ITTs.

**CONCLUSION**

Secure, cost-effective, and diagnostically accurate ITT can be accomplished with lesser samples in shorter period of time. However, this test should be performed in specialised centres by experienced staff.

**PATIENTS’ CONSENT:**
Consents from the parents of the patients were obtained.

**CONFLICT OF INTEREST:**
The authors declared no conflict of interest.
