Abstract

Objectives: Inflammation and inflammatory conditions have been associated with pancreatic cancer risk and progression in a number of clinical, epidemiological, and animal model studies. The goal of the present study is to identify plasma markers of inflammation associated with survival of pancreatic cancer patients, and assess their joint contribution to patient outcome.

Methods: We measured circulating levels of four established markers of inflammation (C-reactive protein (CRP), interleukin-6 (IL-6), soluble tumor necrosis factor receptor type II (sTNF-RII), and macrophage inhibitory cytokine-1 (MIC-1)) in 446 patients enrolled in an ongoing prospective clinic-based study. Hazard ratios (HRs) and 95% confidence intervals (CI) for death were estimated using multivariate Cox proportional hazards models.

Results: Overall mortality was significantly increased in patients in the top quartile of CRP (HR = 2.52, 95% CI: 1.82–3.49), IL-6 (HR = 2.78, 95% CI: 2.03–3.81), sTNF-RII (HR = 2.00, 95% CI: 1.46–2.72), and MIC-1 (HR = 2.53, 95% CI: 1.83–3.50), compared to those in the bottom quartile (P-trend < 0.0001 for all four comparisons). Furthermore, patients with higher circulating concentrations of all four cytokines had a median survival of 3.7 months; whereas, those with lower levels had a median survival of 19.2 months (HR = 4.55, 95% CI: 2.87–7.20, P-trend < 0.0001).

Conclusion: Individual elevated plasma inflammatory cytokines are associated with significant and dramatic reductions in pancreatic cancer patient survival. Furthermore, we observed an independent combined effect of those cytokines on patient survival, suggesting that multiple inflammatory pathways are likely involved in PDAC progression. Future research efforts to target the inflammatory state using combination strategies in pancreatic cancer patients are warranted.

Introduction

Pancreatic ductal adenocarcinoma (PDAC) is the fourth leading cause of cancer death in the US, with a 5-year survival rate of only 8%¹. Several pathologic characteristics obtained at surgery, such as tumor size, resection margin, and number of involved lymph nodes have been associated with reduced survival². However, only 15–20% of PDAC patients are able to undergo resection³. Consequently, identification of additional biomarkers that can be easily assayed in all patients is urgently needed for elucidation of underlying mechanisms of disease progression and development of new therapeutic strategies.

Numerous studies have suggested a role of inflammation in pancreatic cancer development and progression. Cytokines synthesized by the host, tumor cells, and stromal cells play a role in cellular proliferation, angiogenesis, and metastasis. Furthermore, epidemiological studies reveal an association between several inflammation-associated conditions, such as diabetes and obesity, with PDAC survival, further implicating inflammation in PDAC pathogenesis.

Elevated levels of individual inflammatory markers, including C-reactive protein (CRP), interleukine-6 (IL-6), macrophage inhibitory cytokine-1 (MIC-1), and tumor necrosis factor-α (TNF-α), as well as combined scores, such as the Glasgow Prognostic Score (GPS), or CRP to albumin ratio, have been associated with decreased survival in PDAC patients. However, these studies were small and often did not account for potential confounding variables. Moreover, it is not known to what extent these inflammatory pathways, which have distinct roles in tumor development, such as cell proliferation, invasion, angiogenesis, and immune evasion, might be involved in disease progression and patient survival. We therefore evaluated the individual and combined association of these four markers of inflammation with patient survival in a large prospective study of well-characterized PDAC patients.

Materials and methods

Study population

Patients were drawn from an ongoing clinic-based study at the Dana-Farber Cancer Institute (DFCI; Boston, MA). All new patients with a diagnosis of PDAC who were seen in the DFCI Gastrointestinal Cancer Center outpatient clinic were prospectively identified and enrolled to this cohort study between December 22, 2004 and June 16, 2014. Patients were eligible for the study if they had pathologically confirmed PDAC and were age 21 or older. The study was approved by the Dana-Farber/Harvard Cancer Center Institutional Review Board. All participants provided informed consent for their biological specimens and clinical data to be used for research.

Pancreatic cancer cases

A total of 1,038 DFCI patients were approached for consent between December 22, 2004 and June 18, 2014, and 743 (72%) agreed to participate (Supplementary Figure 1). Of patients that provided consent, 485 completed a questionnaire on medical history, medication use, lifestyle, and family history. There were no differences between patients who did or did not complete the questionnaire in regards to gender, age at diagnosis, race/ethnicity, or stage at diagnosis. Of the 485 patients who completed the questionnaire, 450 patients provided blood samples at an average of 1.4 months after diagnosis (Table 1). We excluded patients with missing information.

| Characteristics | Pancreatic cancer cases (N = 446) |
|-----------------|----------------------------------|
| **Mean (SD)**   |                                  |

Table 1 Baseline characteristics of pancreatic cancer patients included in the study
about height (n = 1), gender (n = 1), unknown stage at the
time of blood draw (n = 1), and missing inflammatory
cytokine data (n = 1).

Exposure assessment
CRP, MIC-1, and sTNF-RII were assayed in the
laboratory of Dr. Nader Rifai (Boston Children’s Hospital,
Boston, MA). The sTNF-RII is an established surrogate
measurement for TNF-α due to its role in TNF-α sig-
naling, lower diurnal variation, and increased stability in
frozen plasma.15,26 Furthermore, unlike TNF-α levels of
which tend to fluctuate, levels of sTNF-RII are stable over
long periods of time.27 CRP was measured using an
immunoturbidimetric assay (Roche Diagnostics, Indiana-
polis, IN), with a limit of detection of 0.03 mg/L. MIC-1
and sTNF-RII were measured by an ELISA assay (R&D
Systems, Minneapolis, MN), with a sensitivity of 4.36 pg/
ml for MIC-1 and 0.6 pg/ml for sTNF-RII. IL-6 was
measured as part of the 16-plex pro- and anti-
inflammatory cytokine panel (Human Cytokine A
Premixed Magnetic Luminex Performance Assay, R&D
Systems, Minneapolis, MN). The sensitivity of the assay
is 1.11 pg/mL. Coefficients of variation for each assay were
calculated using 10% blinded duplicate samples, and
ranged from 2.5% for CRP to 6.1% for sTNF-RII.
Laboratory personnel was blinded to patient status.

Covariate assessment
Data on patient and disease characteristics, such as
age at time of blood draw, albumin levels, gender, body
mass index (BMI), treatment status at time of blood draw,
date of diagnosis, stage, treatment history, and date of death were extracted from the medical record. Information on race, smoking status, physical activity, and aspirin and non-
steroidal anti-inflammatory drug (NSAID) use at time of
blood draw were extracted from the self-administered
questionnaire. GPS was calculated as previously
described9,24.

Statistical analysis
All inflammatory cytokines were log-transformed to
improve normality. Correlation between cytokines was ana-
yzed using Spearman correlation. We used the Wilcoxon
rank-sum or Kruskal–Wallis test to evaluate differences in
cytokine levels between two or more groups of interest.

We used the Cox proportional hazards model to evalu-
ate the hazards ratios (HRs) and 95% confidence inter-
vals (CIs) for mortality. Person-time was calculated as
time between blood collection and death or last follow-up
(November 16, 2016). To test the proportionality of
hazards assumption, we evaluated the cross product of
time and inflammatory cytokines. This test revealed a
violation of the proportionality of hazards assumption
which was addressed by including an interaction term
between time and cytokine levels in the models, allowing
calculation of HRs for different time points. Inflammatory
cytokines were modeled as quartiles. To evaluate the
trend of the association between inflammatory cytokines
and survival across quartiles, we used the median of each
quartile as a continuous variable in the model. In multi-
variate models, we adjusted a priori for age at blood col-
collection, gender, grade (well differentiated, moderately
differentiated, poorly differentiated, undifferentiated,
unknown), cancer stage (localized/no evidence of disease,
locally advanced, metastatic), treatment status (treatment
naive, on treatment, post treatment), number of meta-
static sites, BMI (continuous), and physical activity (con-
tinuous) at time of blood collection. We additionally
examined potential confounding by smoking, aspirin use,
NSAID use, and diabetes status at time of blood
collection.

To investigate whether the combination of cytokine
concentrations is more strongly related to mortality than
each individual cytokine alone, we also evaluated the
association between a combined inflammatory cytokine
score and mortality. We calculated this combined score
by summing the number of cytokines with levels above
the population median. The score therefore ranged from 0
(no cytokines above the median) to 4 (all four cytokine
levels above the median).

To compare discrimination between different survival
models, we calculated the overall C-index. This metric is
an extension of the receiver operating characteristic for
the Cox proportional hazard model.28

We performed subgroup analyses to examine potential
effect modification by age (<median of 64.5 years, ≥64.5
years), gender, BMI (<25 kg/m², ≥25 kg/m²), diabetes (yes
vs. no), smoking status (never vs. ever smoker), regular
aspirin use (yes vs. no), grade of differentiation (well/
moderately vs. poorly differentiated/undifferentiated),
and metastatic status (non-metastatic vs. metastatic). We also
performed a stratified analysis by treatment status (treat-
ment naive vs. on/post treatment) for metastatic patients.
### Table 2  Plasma inflammatory biomarkers according to selected patient and tumor characteristics

| Characteristics                        | CRP (mg/L) (n = 437) median (IQ range) | P-value<sup>b</sup> | IL-6 (pg/mL) (n = 427) median (IQ range) | P-value<sup>b</sup> | sTNF-RII (pg/mL) (n = 423) median (IQ range) | P-value<sup>b</sup> | MIC-1 (pg/mL) (n = 434) median (IQ range) | P-Value<sup>b</sup> |

only. Statistical interaction was evaluated by including a cross-product term containing the stratification variable and inflammatory cytokine level (as quartiles) into the model and performing the likelihood ratio test.

Kaplan–Meier method and log-rank tests were used to illustrate and analyze survival curves. Statistical analyses were performed using SAS software (version 9.4; SAS Institute, Cary, NC). All P-values were two-sided.

Results
Characteristics of the study population are shown in Table 1. The study included 211 female (47%) and 235 (53%) male participants. The mean age at diagnosis was 64.1 years. At the time of blood draw, 3% of patients had localized disease, 22% had locally advanced disease, 61% had metastatic disease, and 14% of patients had no evidence of disease following surgical resection. Most patients (53%) were treatment naïve at the time of blood draw, 37% were on active treatment with chemotherapy and/or radiation, and 11% were post treatment.

Median survival time in the entire patient cohort was 9.7 months (30.1 months for patients with no evidence of disease following surgical resection, 19.3 months for those with locally advanced tumors, and 6.5 months for those with metastatic disease). Median follow-up was 9.3 months; at last follow-up, 413 patients (92.6%) had died.

We observed significant, but weak to moderate, correlations between cytokines, with correlation coefficients ranging from 0.12 (IL-6 and sTNF-R1I) to 0.41 (MIC-1 and sTNF-R1I) (Supplementary table 1). CRP levels differed significantly by time between diagnosis and blood draw, BMI, stage, and grade (Table 2). IL-6 levels were higher in regular aspirin users and patients with higher BMI. sTNF-R1I levels were higher among older patients and patients with poorly differentiated and undifferentiated tumors. MIC-1 levels differed significantly by age, gender, time between diagnosis and blood draw, cancer stage, presence of diabetes, aspirin use, and treatment status.

For each measured cytokine, patients with levels in the highest quartile had significantly worse survival (log-rank P-value <0.0001) (Fig. 1a–d). In the multivariate model, compared to patients in the lowest quartile, the mortality hazard of patients in the highest quartiles at the median survival time of 9.5 months was 2.52 (95% CI: 1.82–3.49) for CRP, 2.78 (95% CI: 2.03–3.81) for IL-6, 2.00 (95% CI: 1.46–2.72) for sTNF-R1I, and 2.53 (95% CI: 1.83–3.50) for MIC-1 (Table 3). Moreover, there was a significant linear trend across quartiles (P-trend <0.0001 for all four cytokines). Further adjustment for diabetes, smoking, aspirin use, and non-aspirin NSAID use did not alter the associations (data not shown). We observed similar HRs for death across cytokine quartiles at 6 and 12 months (Supplementary Tables 2 and 3).

We also examined the association between CRP levels and mortality using the conventional CRP cutoff of 10 mg/L. Compared to patients with CRP ≤ 10 mg/L, those with CRP >10 mg/L had a twofold increase in the risk of death (multivariate HR: 2.00, 95% CI: 1.62–2.47). When simultaneously adjusting for all four cytokines in the multivariate model, we observed a continued significant mortality hazard for patients in the highest quartile of CRP (HR: 1.59, 95% CI: 1.07–2.37), IL-6 (HR: 1.80, 95% CI: 1.23–2.65), and MIC-1 (HR: 1.80, 95% CI: 1.22–2.67), while the association between sTNF-R1I and survival was no longer significant (HR: 1.10, 95% CI: 0.75–1.59). Compared to patients with an inflammatory score of 0 and median survival 19.2 months, those with a score of 4 had a median survival of only 3.7 months and adjusted HR of 4.55 (95% CI: 2.87–7.20; P-trend <0.0001) (Table 4, Fig. 1e).

The model including CRP had a discriminatory index of 0.80 (95% CI: 0.71–0.88), comparable to those of GPS (C-index = 0.76, 95% CI: 0.66–0.85) and CRP to albumin

---

**Notes:**

CRP, C-reactive protein; IL-6, interleukin-6; MIC-1, macrophage inhibitory cytokine-1; sTNF-R1I, tumor necrosis factor receptor 2; IQ, interquartile range; BMI, body mass index; MET-hr, metabolic equivalent of task-hour; NED, no evidence of disease; NSAID, nonsteroidal anti-inflammatory drug.

aCut point determined by the median value.

bCalculated using Wilcoxon rank-sum, or Kruskal–Wallis test.

Includes chemotherapy and radiation.

Bold value denotes significance P-value < 0.05.
Fig. 1 Patient survival by quartiles of inflammatory cytokines. A combined inflammatory score was created by adding number of inflammatory markers with the value above the population median.
The significant association between increasing cytokine levels and worse mortality was consistent across most subgroups of known prognostic characteristics (Table 5). We observed a significant interaction between CRP and BMI (P-interaction = 0.03), and between CRP and aspirin use (P-interaction = 0.001), with association with worse mortality being stronger among patients with BMI ≤25 kg/m² and among aspirin users. To evaluate whether higher levels of inflammatory cytokines simply reflect a greater burden of disease, we adjusted for disease stage, number of metastatic sites and CA19-9 levels in the multivariate model and observed no
Discussion

In this large prospective clinic-based study of 446 PDAC patients, subjects with higher levels of each of CRP, IL-6, and MIC-1 experienced a significant increase in overall mortality. Moreover, patients with elevations of all four markers combined had the largest comparative increase in mortality, suggesting involvement of multiple activated inflammatory pathways in PDAC progression. Compared to patients with all cytokines below the population median, those with all four cytokines above the population median had an almost fivefold increased hazard of death, with median survival of 4 vs. 19 months. These associations were independent of known prognostic factors, such as tumor stage, grade, number of metastatic sites, and CA19-9 levels. Furthermore, except for sTNF-RII, the effects of these cytokines on survival are mutually independent.

The inverse associations of CRP and IL-6 with patient survival in our study are consistent with previously reported findings. We further showed that the associations of these two cytokines are independent from each other, as well as from MIC-1 and sTNF-RII. While we observed a significant association between survival and sTNF-RII, a surrogate for TNF-α, the association was attenuated after adjusting for CRP, IL-6 and MIC-1. This therefore argues against an independent effect of TNF-α on survival, as has been previously suggested. Our finding of decreased survival among patients in the top quartile of MIC-1 compared to those in the lowest quartile is also consistent with previous studies; however, distinct from those prior studies, we were able to comprehensively adjust for potential confounders. We also found that the influence of high-MIC-1 levels was independent of CRP, IL-6, and sTNF-RII. To our knowledge, no previous studies have assessed the combined contribution of those four inflammatory cytokines on PDAC patient survival.

Several explanations have been proposed to address the relationship between inflammatory cytokines and survival. High levels of circulating cytokines may result from the systemic response of host to tumor, reflecting the tumor burden. CRP is produced by the liver as part of the acute phase response, and its levels correlate with cancer progression, both by acting directly on tumor cells and by modifying the tumor microenvironment. IL-6 exerts its protumorigenic effects by activating several signaling pathways involved in PDAC, such as JAK-STAT3, Ras-MAPK, and PI3K-Akt, leading to increased cellular proliferation, angiogenesis, and metastatic potential. IL-6 is one of the key factors in the development of muscle wasting, or cachexia, which is responsible for about one third of PDAC-associated deaths and decreased response to treatment. Furthermore, it was shown that IL-6 leads to formation of desmoplastic stroma, a dense extracellular matrix which acts as a physical barrier for effective drug delivery. MIC-1, a member of the human transforming growth factor (TGF)-β superfamily, has both anti- and protumorigenic roles in colon, breast, prostate, and melanoma cancers.

\(^a\) Hazard ratios are adjusted for age, sex, BMI, history of diabetes, metastatic disease, number of metastatic sites, grade, smoking status, and regular aspirin use.

\(^b\) Hazard ratios are adjusted for age, sex, BMI, history of diabetes, metastatic disease, number of metastatic sites, grade, smoking status, and regular aspirin use.

\(^c\) Hazard ratios are adjusted for age, sex, BMI, history of diabetes, metastatic disease, number of metastatic sites, grade, smoking status, and regular aspirin use.

\(^d\) P-values for interaction terms indicate differences in the association of the biomarker with death by subgroup.

\(^e\) Number of metastatic sites is grouped into two categories: 1 or >1.

\(^f\) Regular aspirin use includes only those who took aspirin regularly for at least one year.

\(^g\) Treatment status includes only those who received the standard of care treatment.

Official journal of the American College of Gastroenterology
While differences in MIC-1 levels between PDAC patients and healthy controls have previously been reported, little is known about the molecular pathways underlying this association. Furthermore, it was shown that both IL-6 and MIC-1 attenuate T-cell-mediated anti-tumor immune response. In PDAC, as well as other cancers, MIC-1 overexpression is associated with increased resistance to chemotherapy drugs. However, it is unlikely that resistance to treatment explains the effect of MIC-1 in our study, since there was no difference in survival in treatment naive or on/post treatment group by MIC-1 levels (Table 5).

Our results carry multiple potential clinical and translational implications. First, CRP, IL-6, and MIC-1 assays are inexpensive and non-invasive. Therefore, their prognostic potential should be further investigated in future studies. Furthermore, they could be used to identify patients who may benefit most from anti-inflammatory strategies. Indeed, interest in the use of circulating inflammatory cytokines as predictors of treatment efficacy was first suggested by the RECAP trial, a randomized phase II study of capecitabine with or without ruxolitinib (JAK/STAT inhibitor) in patients with refractory PDAC that showed a survival benefit with ruxolitinib in patients with high CRP or modified GPS. Unfortunately, subsequent phase III trials did not confirm this finding, but have led to research efforts in other novel inflammation-mediated pathways, including inhibitors of TBK1, which regulates a KRAS-driven autocrine cytokine circuit, immunomodulatory agents such as CCR2 antagonists (ClinicalTrials.gov identifier NCT02732938), and vitamin D receptor VDR analogs, which have been shown to reprogram the tumor microenvironment. It is conceivable that levels of inflammatory cytokines may play a future role in helping to select the patients who are most likely to benefit from these novel agents.

Advantages of our study include the prospective study design, large number of patients, as well as detailed information on clinical, pathological, treatment, and lifestyle factors. We were also able to evaluate a variety of inflammatory cytokines singly and in combination. However, several limitations exist. We were not able to evaluate pancreatic cancer-specific mortality, but 95% of pancreatic cancer patients present with incurable disease at diagnosis, therefore it is highly unlikely that our patients died of other causes. Furthermore, our study consisted of predominantly white participants treated at a tertiary academic center, and therefore our results may not be generalizable to the overall population of pancreatic cancer patients. Reassuringly, though, the median survival of our study population is reflective of PDAC patients overall. Finally, while circulating inflammatory cytokines have the advantage of being easily measurable and accessible in patients, plasma levels may not adequately reflect inflammatory activity within the tumor or its microenvironment. Fortunately, recent technological advances that allow tumor RNA sequencing in bulk or on single-cell populations will pave the way toward elucidating the exact origin and mechanism of the high-inflammatory state of PDAC patients.

In conclusion, increasing levels of circulating inflammatory cytokines were associated with significantly decreased survival of patients with pancreatic cancer in this large prospective clinic-based study. The potential...
prognostic value of these markers, as well as their utility for patient selection for novel anti-inflammatory and immunomodulatory agents, should be evaluated in future studies. Moreover, efforts to understand the pathogenesis of the high-inflammatory state and development of novel agents to decrease inflammation in PDAC patients are warranted.

Study Highlights

What is current knowledge
- Inflammation and inflammatory conditions have been associated with increased risk of pancreatic cancer
- Individual inflammatory cytokines have been associated with survival of pancreatic cancer patients

What is new here
- The effect of inflammatory cytokines on pancreatic cancer patient survival is mutually independent and additive, suggesting that multiple inflammatory pathways are involved in PDAC progression
