ABSTRACT: This paper reports a room temperature visible light photocatalyzed method for the C–H amination of arenes and heteroarenes. A key enabling advance in this work is the design of N-acyloxyphthalimides as precursors to nitrogen-based radical intermediates for these transformations. A broad substrate scope is presented, including the selective meta-amination of pyridine derivatives. A radical aromatic substitution mechanism is proposed.

Aromatic and heteroaromatic amines are widely prevalent in pharmaceuticals, agrochemicals, and organic materials. These molecules are most commonly prepared by nucleophilic aromatic substitution, transition-metal-catalyzed cross-coupling, or reduction of nitroarenes. While all of these methods have proven valuable for a variety of applications, they suffer from the disadvantage of requiring prefunctionalized starting materials.

Over the past decade, there has been increasing effort to circumvent the requirement for prefunctionalization by achieving the direct C–H amination of aromatic substrates. The vast majority of synthetically useful arene C–H amination methods involve either ligand-directed or intramolecular C–N bond formation. In contrast, intermolecular C–H amination of simple arenes/heteroarenes remains significantly more challenging. Current methods suffer from significant limitations, including the requirement for high temperatures, UV photolysis, and/or stoichiometric quantities of expensive oxidants. Additionally, some reported systems require specialized catalyst scaffolds. Finally, competitive formation of C–H oxygenation or C–H bromination side products is observed in several cases.

We sought to develop a new photocatalytic method for the intermolecular C–H amination of arenes and heteroarenes that would address many of the challenges described above. Our approach to this problem was inspired by the work of Skell, who demonstrated that UV photolysis of N-bromophthalimide releases PhthN and Br, which can participate in competing C–H amination and C–H bromination of the benzene solvent (Scheme 1). We hypothesized that visible light photocatalysis could be used to form analogous nitrogen-based radical intermediates under much milder conditions from readily available starting materials (Scheme 2). We anticipated that this could render these reactions synthetically useful by (1) precluding the concomitant formation of Br, (2) affording enhanced yields of the desired aryl amines, and (3) enabling an expansion of the (currently extremely narrow) substrate scope.

Our initial efforts toward this goal focused on the use of N-acyloxyphthalimides (1) as aminating reagents. These compounds can be readily synthesized from N-hydroxyphthalimide and carboxylic acid derivatives. In addition, several reports have shown that they undergo visible light photocatalyzed reduction. With R = alkyl, this reduction results in decarboxylative fragmentation to release CO₂ and PhthN. With R = o-ethyl (Scheme 2b). The PhthN· could then participate in C–H amination of diverse substrates.

To test this hypothesis, we examined the C–H amination of benzene with a series of electronically different N-acyloxyphthalimides in the presence of 5 mol % of commercially available...
Ir(ppy)$_3$ and visible light. As shown in Table 1, entry 1, acyloxyphthalimide 1a (with R = CH$_3$) did not react to afford detectable quantities of C–H amination product 2. This is consistent with literature reports showing that alkyl-substituted acyloxyphthalimides undergo selective decarboxylative fragmentation via pathway $a$ (Scheme 2). However, as predicted, increasing the electron-withdrawing character of the R substituent resulted in the formation of product 2 in modest to excellent yield (entries 2–7). In particular, trifluromethylacyloxyphthalimide (1g), which is available in a single step from commercial N-hydroxyphthalimide and trifluoroacetic anhydride, afforded 81% yield of 2.

Control reactions confirm that C–H amination product 2 is not formed in the absence of either photocatalyst or visible light (Table S1). Further optimization revealed that the photocatalyst loading can be decreased to as low as 0.5 mol %, while maintaining a yield of 55%. Furthermore, the reaction can be conducted with benzene loadings as low as 1 equiv relative to 1g, albeit with a decrease in chemical yield to 23%.

We next examined the scope of arenes that participate in this C–H amination reaction.

| Table 1. Visible Light Photocatalyzed C–H Amination of Benzene with N-Acyloxyphthalimide Derivatives |
|---|
| entry | R | yield$^{a}$ |
| 1 | CH$_3$ (1a) | nd$^{b}$ |
| 2 | $p$-MeOCH$_3$ (1b) | 7% |
| 3 | Ph (1c) | 8% |
| 4 | $p$-CF$_3$Ph (1d) | 20% |
| 5 | C$_6$F$_5$ (1e) | 53% |
| 6 | CH$_3$CF$_3$ (10) | 62% |
| 7 | CF$_3$ (1g) | 81% |

$^{a}$General conditions: 1 (1 equiv), Ir(ppy)$_3$ (5 mol %), benzene (10 equiv), MeCN (0.1 M in 1), visible light, 24 h, rt. Yields determined by GC. $^{b}$nd = not detected.

Table 2. Arene Substrate Scope$^{a}$

| Table 2. Arene Substrate Scope$^{a}$ |
|---|---|---|
| (1g) | CF$_3$ | 56% |
| (10) | CF$_3$ | 42% |
| (11) | 52% |
| (12) | 79% |
| (13) | 69% |
| (14) | 51% |
| (15) | 49% |
| (16) | 45% |
| (17) | 71% |
| (18) | 57% |
| (19) | 66% |
| (20) | 79% |
| (21) | 51% |
| (22) | 32% |
| (23) | 41% |

$^{a}$Conditions: 1g (1 equiv), Ir(ppy)$_3$ (5 mol %), arene (10 equiv), MeCN (0.1 M in 1g), visible light, 24 h, rt. Major product shown. Yields and selectivities are of isolated products.

Table 3. Heteroarene Substrate Scope$^{a}$

| Table 3. Heteroarene Substrate Scope$^{a}$ |
|---|---|---|
| (1g) | CF$_3$ | 56% |
| (10) | CF$_3$ | 42% |
| (11) | 52% |
| (12) | 79% |
| (13) | 69% |
| (14) | 51% |
| (15) | 49% |
| (16) | 45% |
| (17) | 71% |
| (18) | 57% |
| (19) | 66% |
| (20) | 79% |
| (21) | 51% |
| (22) | 32% |
| (23) | 41% |

$^{a}$Conditions: 1g (1 equiv), Ir(ppy)$_3$ (5 mol %), heteroarene (10 equiv), MeCN (0.1 M in 1g), visible light, 24 h, rt. Major product shown. Yields and selectivities are of isolated products. $^{b}$Heteroarene (20 equiv), MeCN (0.2 M in 1g).

hypothesized that it might be compatible with heterocycles. Indeed, as summarized in Table 3, electron-rich heterocycles such as furan, thiophene, and 1-methylpyrrole all underwent C–H amination in moderate to good yield under our optimal conditions (products 13–15). Importantly, these substrates are not stable in the presence of the high temperatures and/or strong oxidants required for many previously reported C–H amination methods. Both electron-rich and electron-deficient pyridine derivatives are
also viable substrates, providing meta-substituted products with good selectivity (17−23). Notably, there does not appear to be any catalyst inhibition with these pyridine substrates, presumably because the Ir contains strongly coordinating cyclometalated phenylpyridine ligands.

A proposed catalytic cycle for the current transformation is shown in Scheme 3. This cycle begins with photoexcitation of Ir(ppy)$_3$ to generate Ir(ppy)$_3^*$ (step a). Single electron transfer from Ir(ppy)$_3^*$ to 1g then results in fragmentation of the N-acloyloxyphthalimide to generate an N-centered phthalimidyl radical (PhthN•), trifluoroacetate anion, and Ir(ppy)$_3^*$ (step b). The PhthN• next adds to the arene, forming a neutral radical intermediate (step c) which can be oxidized by Ir(ppy)$_3^*$, regenerating the photocatalyst (step d). The trifluoroacetate anion, formed upon reductive cleavage of the N−O bond, deprotonates the cationic Wheland intermediate, providing 1 equiv of aminated product and trifluoroacetic acid (step e).30

Preliminary mechanistic studies show that irradiation with visible light is necessary for reaction progress. The C−H amination ceases when the reaction is removed from light and only recommences when the light is turned back on (see Scheme S1 for full details of this experiment).31 This experiment is consistent with the mechanism proposed in Scheme 3. Although a radical chain process cannot be completely ruled out, these results indicate that any chain propagation is very short-lived.18

In conclusion, we describe a mild photocatalytic method for the C−H amination of arene and heteroarene substrates. A key enabling advance in this work is the design of N-acloyloxyphthalimides as precursors to nitrogen-based radical intermediates for these transformations. Our C−H amination method addresses several key limitations of prior work in the field, as it circumvents the requirement for excesses of expensive oxidants as well as elevated temperatures. The heterocyclic amine products are particularly common in biologically active molecules. Ongoing studies are focused on applying this reaction to more complex molecules as well as gaining detailed insights into the reaction mechanism.
