Abstract

This paper introduces the dynamics of charged particles in a radiofrequency trap in a very general manner to point out the differences between the dynamics in a quadrupole and in a multipole trap. When dense samples are trapped, the dynamics is modified by the Coulomb repulsion between ions. To take into account this repulsion, we propose to use a method, originally developed for particles in a Penning trap, that models the ion cloud as a cold fluid. This method can not reproduce the organization of cold clouds as crystals but it allows one to scale the size of large samples with the trapping parameters and the number of trapped ions, for different linear geometries of trap.

1. Introduction

Quadrupole radiofrequency traps appear to be the obvious choice for most applications where charged particles need to be trapped, cooled and manipulated by laser interactions. Optical frequency metrology and quantum information processing give examples of such a control of the ion motion by atom–laser interaction as shown in several contributions to this special issue. Up to now, all the protocols make use of the harmonic nature of the potential induced by the radiofrequency field and were demonstrated with one or few ions. On the other hand, higher order radiofrequency traps are efficiently used with large samples where buffer gas cooling is preferred to laser cooling. This is the case, for example, for microwave frequency standards working with large samples of Hg+ ions [1, 2] or with experiments studying cold reactions with molecules [3, 4]. In the prospect of new experiments where one could think of applying quantum information processing methods to a larger sample (of atomic or molecular ions), it may be useful to consider using higher order radiofrequency traps than the usual quadrupole trap. The first purpose of this paper is to give a general background about the dynamics of ions in radiofrequency traps to point out the differences between the dynamics inside a quadrupole and a multipole trap (here we call a multipole trap a linear radiofrequency trap with a higher symmetry order than a quadrupole). The second objective of this paper is to present a mean-field approach already used for particles in Penning traps and called the nonneutral plasma. Using this method, it is possible to scale the size of a trapped sample with the relevant physical parameters of the problem. This general approach is useful to understand what is so special about the quadrupolar geometry even when large samples are trapped. This paper is organized in two parts, the first one describes the dynamics of single charged particle in a radiofrequency field of very general geometry. The second part introduces the mean-field approach that allows one to take into account the Coulomb repulsion in large samples. This model is used in the linear geometry to establish relations between the trapping parameters and the characteristics of the trapped sample.

2. General description of radiofrequency trapping

2.1. The most general case

Let us try to get some insights into the dynamics of trapped ions (mass \( m \) and charge \( q \)) starting with a non-specific geometry. The development presented here is greatly inspired from a broad review written by Gerlich about multipoles and their use to study ion–molecule reaction dynamics [5]. Let us assume
that the potential between a set of electrodes can be written as the sum of a static voltage $\Phi_s(r)$ and a radiofrequency voltage $\Phi_{rf}(r, t)$ oscillating at frequency $\Omega$ and responsible for the effective trapping of the charged particle. The motion of a single ion is then governed by the local electric field

$$E(r, t) = \nabla \Phi_s(r) + \nabla \Phi_{rf}(r, t) = E_s(r) + E_0(r) \cos(\Omega t).$$

(1)

To compute the trajectory of this ion, the difficulty lies in the integration of the equations of motion in a time varying electric field. So we first assume that there is no static electric field ($E_s(r) = 0$). If the electric field were homogeneous, the motion would revert to the rf-driven oscillation

$$r(t) = -\frac{qE_0}{m\Omega^2} \cos(\Omega t) = -a \cos(\Omega t),$$

(2)

where $a$ is the amplitude of this oscillation. As $E_0(r)$ is non-homogeneous, this amplitude varies in space and the motion can be split into two contributions: the motion driven by the rf field $R_1(t) = -a(t) \cos(\Omega t)$ and a slower motion $R_0(t)$ induced by the variation of the amplitude of the radiofrequency field. The local electric field can then be expanded as

$$E_0(r(t)) = E_0(R_0) - (a(t) \cdot \nabla) E_0(R_0) \cos(\Omega t) + \cdots.$$  

(3)

The resolution proposed here for the dynamical equations relies on two approximations:

(i) the first order expansion of $E_0$ around $R_0$ in equation (3) and

(ii) the adiabatic approximation which assumes that the typical evolution time scale of $a$ and $R_0$ is far longer than the rf period.

In this frame of approximations, the slow dynamics is determined by

$$m \ddot{R}_0 = -\frac{q^2}{4m\Omega^2} \nabla E_0^2$$

and, as far as $R_0(t)$ is concerned, it is as if the particle is trapped in a static potential well, called the pseudo-potential:

$$V^+(r) = \frac{q^2 E_0^2(r)}{4m\Omega^2}.$$  

(4)

(5)

Building a pseudopotential well implies $\nabla E_0^2(r) > 0$ in the three directions. In practice, the fulfillment of this condition is not sufficient to assure the stability of the ion’s trajectory. A conservative stability criterion is given by a local adiabaticity criterion, introduced by Teloy and Gerlich [3, 5], and defined by the relative variation of $E_0$ seen over the amplitude of the driven motion oscillation:

$$\eta_{ad} = \frac{2|a \cdot \nabla E_0|}{|E_0|} = \frac{2q|\nabla E_0|}{m\Omega^2}.$$  

(6)

This adiabaticity parameter depends on the location in the trap except for the particular case of quadratic radiofrequency voltage for which $\nabla E_0$ is homogeneous. In the multipole case, numerical simulations and experimental observations mentioned by Gerlich [5] show that the empirical limit $\eta_{ad} < 0.3$ guarantees adiabaticity in most cases. A more recent experimental study of the loss mechanism in a 22-pole trap [6] complementary to a more general model of effective trapping volume for multipole [7] has demonstrated stability up to $\eta_{ad} < 0.36 \pm 0.02$. A safe criterion for stability could then be $\eta_{ad}(R_{max}) < 0.34$.

If the static electric field is switched on again, according to the superposition theorem, the motion is governed by the effective static potential

$$V^+(r) = \frac{q^2 E_0^2(r)}{4m\Omega^2} + q\Phi_s(r).$$  

(7)

The rf-driven motion (also called micromotion) $R_1(t)$ is deduced from the motion in the pseudopotential (called macromotion):

$$R_1(t) = -\frac{qE_0(R_0)}{m\Omega^2} \cos(\Omega t).$$  

(8)

and its amplitude is proportional to the local rf-electric field. As this electric field must increase with $R_0$ for effective trapping, the micromotion amplitude increases with the distance from the trap centre. As this driven motion cannot be cooled, the only way to reduce this amplitude is to keep the ion at the node of the electric field.

2.2. Focus on the linear trap

In most experiments requiring a precise control of the dynamics and kinetic energy of the ions, micromotion is a side effect that can bring a large contribution to the Doppler effect and reduces the precision reached on the kinetic energy of the ions. In a linear geometry where a radiofrequency voltage is applied only in the transverse plane with a translation symmetry along the remaining axis, the node of the radiofrequency electric field is the symmetry axis. When large samples are trapped, it gives rise to a reduced micromotion compared to spherical traps, as the ions are closer to the node of the electric field. In this section, we assume such a linear geometry where the trap consists of $2k$ equally spaced rods as electrodes for transverse trapping and where the confinement along the axis of symmetry is reached by a static potential (the geometry of the electrodes used for the axial confinement is not very relevant in this paper).

As a first step, we ignore this static potential and assume that voltages $+V(t)/2 = U/2 - V_0/2 \cos(\Omega t)$ and $-V(t)/2$ are applied on alternate electrodes (so the voltage difference between neighbouring electrodes is $V(t)$), note that in Gerlich’s paper this voltage is chosen to be $2V(t)$). The $2k$ electrodes are rods located at the same distance $r_0$ from the trap axis and solutions of the Laplace equation $\Delta \Phi = 0$ are linear combinations of

$$\Phi_k(r, t) = \Phi_0(t)(r/r_0)^k \cos(k\theta),$$  

(9)

where $(r, \theta)$ are the polar coordinates in the $(x, y)$ plane. The contribution of each order $k$ is fixed by the boundary conditions defined by the shape and position of the electrodes. Figure 1 shows the equipotential lines in the transverse plane of an ideal multipole where only one contribution of defined symmetry order defines the potential. This potential distribution can be realized ideally if the electrode surfaces exactly match the equipotential surfaces. Deriving the radiofrequency electric
field generated by such a potential, the equations governing the motion in the plane of a 2k-pole are

\[
\begin{align*}
\dot{x}/r_0 &= F_k(t)(r/r_0)^{k-1} \cos (k-1)\theta = 0 \\
\dot{y}/r_0 &= F_k(t)(r/r_0)^{k-1} \sin (k-1)\theta = 0
\end{align*}
\] (10)

with \(F_k(t) = kqU_p/(2mr_0^2) - kqV_0/(2mr_0^2)\cos(\Omega t)\). As an example, let us have a look at the equations of motion of an ion in an octupole (2k = 8):

\[
\begin{align*}
\dot{x} + F_3(t)(x^3 - 3y^2x)/r_0^2 &= 0 \\
\dot{y} - F_4(t)(y^3 - 3x^2y)/r_0^2 &= 0.
\end{align*}
\] (11)

These equations are nonlinear and coupled. The nonlinearity makes the stability of individual trajectories sensitive to their initial conditions. As a consequence, it is not possible to define absolute stability conditions based only on the working parameters of the trap. An estimation of the local stability is provided by the adiabaticity criterion (equation (6)). For a 2k-pole, it increases like \(r^{k-2}\) and is uniform only in the quadrupolar case (2k = 4):

\[
n_{ad} = k(k-1)\frac{qV_0r^{k-2}}{2m\Omega^2r_0^2}.
\] (12)

In a quadrupole, and only in a quadrupole, the equations of motion take the simple forms

\[
\begin{align*}
\dot{x} - F_2(t)x &= 0 \\
\dot{y} + F_2(t)y &= 0,
\end{align*}
\] (13)

which are linear and uncoupled for \(x\) and \(y\). The introduction of the reduced time scale \(\xi = \Omega t/2\) leads to the well-known Mathieu equation

\[
\frac{d^2u}{d\xi^2} + (\omega_u^2 - 2q_u \cos(\Omega \xi))u(\xi) = 0
\] (14)

(\(u = x, y\)), which belongs to the family of differential equations with periodic coefficients. Solutions of this equation can be found in many textbooks [8, 9]. The solutions have the form

\[
u(t) = \lambda e^{i\omega_u t} \sum \alpha_n e^{i\omega_n \xi} + \mu e^{-i\omega_u t} \sum \beta_n e^{-i\omega_n \xi}
\] (15)

with \(\omega_u = \beta_u \Omega/2\), \(\beta_u\) depending only on the Mathieu parameters \(a_u\) and \(q_u\) through continuous fractions. \(a_u\) and \(q_u\) depend on the trapping parameters by

\[
\begin{align*}
q_x &= \frac{2qV_0}{m\Omega^2r_0^2}, & q_y &= \frac{-2qV_0}{m\Omega^2r_0^2} \\
\alpha_c &= \frac{4qU_p}{m\Omega^2r_0^2}, & \alpha_y &= \frac{4qU_p}{m\Omega^2r_0^2}.
\end{align*}
\] (16)

These solutions are stable if \(0 \leq \beta_u \leq 1\). This condition defines areas in the plane defined by \((a_u,q_u)\): the stability regions. In practice and because of technical limitations, radiofrequency traps are operated in the lowest stability region (the one including (0, 0)).

The solutions of the Mathieu equation can be expanded in the lowest order approximation which requires \((|a_u|,|q_u|) \ll 1\) and implies that \(\beta_u \ll 1\). In this limit \(\beta_u = \sqrt{a_u + q_u^2/2}\) and

\[
u(t) = U \cos(\omega_u t) \left(1 + \frac{4q_u}{2} \cos \Omega t\right).
\] (18)

This is exactly what we would obtain using the pseudopotential well resulting from the adiabatic approximation. It says that the main motion (or macromotion) is a harmonic oscillation of frequency \(\omega_u\), perturbed by the driven radiofrequency motion (or micromotion). The amplitude of this micromotion is proportional to the harmonic oscillation amplitude and to the Mathieu equation parameter \(q_u\).

The Mathieu equations, or more generally the equations of motion given by equation (10), are strictly true for a single ion in an ideal trap and do not include the Coulomb repulsion between ions. When several ions are trapped, the correlations between ions (often called space charge effect in its mean-field approach) can be ignored for warm enough or very dilute samples where the averaged Coulomb repulsion is low compared to the kinetic energy. The coupling parameter \(\Gamma = q^2/(4\pi\epsilon_0ak_BT)\), the ratio of the average nearest-neighbour Coulomb repulsion energy and the thermal energy, quantifies this competition between correlation and thermal motion (the usual definition sets \(a\) as the Wigner–Seitz radius and is related to the density by \(4\pi a^3/3 = 1\)). For low \(\Gamma\) (\(\Gamma \ll 1\)), the Coulomb repulsion can be ignored and it is relevant to use the single ion equations of motion to learn about the ion dynamics.
With laser cooling techniques, $\Gamma$ as high as a few hundred can be reached. As soon as $\Gamma \geq 1$, correlations cannot be ignored to calculate dynamics or equilibrium properties of the trapped ions. This problem is widely addressed by two methods. The first one is based on computer simulations of the experiment by calculating the position and velocity of each ion by a Monte Carlo method [10], when only the statistical equilibrium is studied, or by molecular-dynamics simulations [11–13] when information about the dynamics is also required. These computer simulations are an efficient tool to calculate the crystal structure appearing in trapped ions as soon as $\Gamma \geq 100$, depending on the trapping parameter, the number of ions and the temperature [12, 14–16]. It is even possible to include buffer gas or laser Doppler cooling in the model, by an effective damping force [13, 17] or by a stochastic force induced by the momentum kicks in each collision or absorption/emission process [18]. In this paper I wish to present another method which has been developed for electrons or ions in Penning traps but which is very relevant for ions in radiofrequency traps, using a model for the atomic sample called the non-neutral plasma. This model uses a mean-field approach where the ion–ion Coulomb repulsion is taken into account by the total field created by the charge distribution. One can show [19] that the equilibrium state of such a system in a harmonic pseudopotential is equivalent to that of a one component plasma (OCP), a model system where the charged particles are embedded in a neutralizing background charge. It allows one to calculate the density and size of trapped charged samples in the dense and cold limit, a requirement which fits very well with laser-cooled atoms. Contrary to the molecular dynamics or Monte Carlo methods, it cannot reproduce the internal Coulomb crystal structure observed in experiments but it is of great help to scale the size of a linear trap with the desired number of ions. This is the question that I try to answer in the following section. Most of the concepts introduced here can be found in the review by Dubin and O’Neil [19] concerning the thermal equilibrium states of trapped non-neutral plasmas.

3. The mean-field approach

When a large sample is trapped, a mean-field approach can be used to study the global behaviour of the sample. This treatment has been mostly used in the context of Penning traps, for electrons or ions [20, 21] but also in 3D radiofrequency quadrupole traps (or Paul traps) [22]. In this model, a thermal equilibrium state is assumed and the sample is treated like a cold fluid. This approximation holds if the plasma size is large compared to the Debye length $\lambda_D$. This length characterizes the scale over which a mean-field approach is relevant to treat the Coulomb repulsion. It depends on the density $n$ and temperature $T$ of the plasma as $\lambda_D = \sqrt{k_BT\epsilon_0} / q^2 n$ and decreases for cold and dense plasmas. The cold fluid model allows one also to calculate the aspect ratio (radius over length) of a cloud trapped in a harmonic potential [23]. These predictions have been confirmed experimentally with laser-cooled ions in a Penning trap [24] and in a linear rf quadrupole in the isotropic [25] and anisotropic [26] cases.

In the context of radiofrequency trap, the equilibrium state concept requires us to use the pseudopotential approach to represent the trapping potential. Like in the previous section, we assume a linear geometry but the same points developed here could be applied to a 3D multipole trap. To find an experimental characterization of the thermal equilibrium of an atomic cloud trapped in a 3D octopole trap, the reader should refer to [27] where the density profile is studied by means of laser-induced fluorescence resolved in space. In the linear geometry, the pseudopotential in the transverse plane of an ideal multipole is defined by (see equation (7))

$$V(r) = \frac{q^2 V_0^2}{32\epsilon_0 k} \left( \frac{r}{r_0} \right)^{2k-2} + \frac{q U_s}{2} \left( \frac{r}{r_0} \right)^k \cos k\theta,$$

where $\epsilon_0 = m\Omega^2 r_0^2 / (2k^2)$ is a characteristic energy. In the following, we consider that there is no static voltage $U_j$ applied to the rods but we take into account the static potential required for axial confinement and its effect on the transverse pseudopotential. The total effective potential becomes

$$V^*(r) = \frac{q^2 V_0^2}{32\epsilon_0 k} \left( \frac{r}{r_0} \right)^{2k-2} + \frac{q U_s V_{\text{end}}}{2z_0^2} (2z^2 - r^2),$$

where $k$ is a loss factor depending on the geometry of the end electrodes relative to the rods. It includes all screening effects that can explain the reduction between the potential applied on the end electrodes $V_{\text{end}}$ and that effectively seen by the ions. For $2k = 4$, the shape of the transverse pseudopotential remains quadratic and no major impact is expected from the transverse deconfining effect of the axial confinement. On the contrary, for $2k = 8, 12, \ldots$, the shape of the pseudopotential is modified. The axis of the trap becomes an unstable position and the potential minimum is shifted to $r = r_{\text{min}}$ defined by

$$r_{\text{min}}^{2k-4} = r_0^{2k-2} - \frac{16\epsilon_0 k U_s V_{\text{end}}}{z_0^2 (k-1) q V_0^2}.$$  

We see later that this shift of the potential minimum from the centre of the trap has no effect on the density distribution calculated in the mean-field model.

According to the work of Dubin, Driscoll, O’Neil and Prasad [19, 28, 29] and assuming the ergodic hypothesis, the thermal equilibrium state of a non-neutral plasma with non-negligible correlations can be described by the $N$-particle Gibbs distribution for plasmas as small as $N \geq 100$ (for smaller $N$, fluctuations are too big to identify the average over the microcanonical and the canonical—or Gibbs—distribution). Integrated over the $N$ velocities and $N-1$ positions, the Gibbs distribution gives access to the plasma density distribution $n(r)$:

$$n(r) = \mathcal{N} \exp \left( \frac{-\mathcal{E}(r)}{k_B T} \right),$$

where $\mathcal{N}$ is a normalization constant and $\mathcal{E}(r)$ is the energy of a particle at position $r$. It results from the contribution of the confining potential $V^*(r) = q \phi_T(r)$ and the mean-field Coulomb repulsion potential $q \phi(r)$ created by all the charges surrounding point $r$ (the image charge effect is neglected as we assume the charges are far enough from any conducting surface [30]). The normalization issue can be solved by defining the
density with respect to the density in the centre of the trap \( n(0) = n_0 \):

\[
n(\mathbf{r}) = n_0 \exp[\Psi(\mathbf{r})]
\]

\[
\Psi(\mathbf{r}) = -q k_B T / (\epsilon_0) \left( \phi_T(\mathbf{r}) + \phi_q(\mathbf{r}) - \phi_T(0) - \phi_q(0) \right).
\]

The density distribution and the potential created by the charges are related by the Poisson equation

\[
\Delta \phi_T(\mathbf{r}) = -q n(\mathbf{r}) / \epsilon_0.
\]

This system of equations is then self-consistent but one can get rid of some normalization difficulties by studying only the logarithmic density profile \( \Psi(\mathbf{r}) \) [28, 29] and using equations (24) and (25), one can show that

\[
\Delta \Psi(\mathbf{r}) = q^2 n_0 / k_B T \epsilon_0 \left( \exp[\Psi(\mathbf{r})] - \epsilon_0 / q n_0 \Delta \phi_T \right).
\]

It is obvious from equation (26) that the Debye length relative to the central density \( \lambda_D = \sqrt{k_B T \epsilon_0 / (q^2 n_0)} \) will be the relevant length scale for the density profile. This equation also shows that the static contribution to the effective potential \( V^* \) has no impact on the density profile as this contribution obeys the Laplace equation \( \Delta \phi = 0 \) and that only the pseudopotential associated with the radiofrequency field controls this profile. Equation (26) also points out the difference between quadrupoles and multipoles, regarding the field controls this profile. Equation (26) also shows that the static contribution to the effective potential \( V^* \) has no impact on the density profile as this contribution obeys the Laplace equation \( \Delta \phi = 0 \) and that only the pseudopotential associated with the radiofrequency field controls this profile.

In the following, this ratio \( n_c / n_0 \) is expressed as \( \gamma + 1 \), \( \gamma \) measuring how far the system is from the uniform limit density (\( \gamma > 0 \)). Finally, the differential equation determining the density distribution is

\[
\Delta \Psi(\mathbf{r}, z) = 1 / \lambda_D^2 \left( \exp[\Psi(\mathbf{r}, z)] - \gamma - 1 \right).
\]

To simplify the integration, we introduce the reduced coordinates \( (\rho, \xi) = (r/\lambda_D, z/\lambda_D) \) and solve

\[
\Delta \Psi(\rho, \xi) = \exp[\Psi(\rho, \xi)] - \gamma - 1 = 0.
\]

**Case of a prolate cloud \( L \gg R \).** In the following, we assume that the cloud is prolate and the dependence of the density with \( z \) is negligible compared to its dependence with \( r \). This simplifies the problem to the integration of a one-dimensional differential equation

\[
1 / \rho \partial^2 \Psi / \partial \rho^2 + \partial^2 \Psi / \partial \rho^2 = \exp[\Psi] - \gamma - 1.
\]

To have an insight into the role of \( \gamma \) in this equation, it is useful to look for an approximate solution, valid close to the trap centre. For \( \Psi(\rho) \ll 1 \), \( \exp[\Psi(\rho)] \approx 1 \). In this approximation, the solution of the differential equation (32) is \( \gamma(1 - L_0(\rho)) \) where \( L_0(\rho) \) is the modified Bessel function of order 0. Using the lowest order expansion of \( L_0(\rho) \), one can deduce that for \( \rho^2 \ll 4 / \gamma \), \( \rho(\rho^2) \approx n_0(1 - \gamma \rho^2 / 4) \). So the smaller the \( \gamma \) the larger (in the reduced parameter) the range where the density profile is nearly flat.

Integration of equation (32) (with the limit conditions \( \Psi(0) = 0 \) and \( \Psi(0) = 0 \)) results in the profile \( \Psi(\rho) \) and its exponential \( n(\rho) / n_0 \) which implicitly depends on \( \gamma \). To get real values for the number of trapped ions, the absolute density profile \( n(\rho) \) and the size of the sample, one has to find other relations between the relevant functions and parameters.

- First, in the frame of our approximation, the total number of ions is

\[
N = \int_0^L \int \rho dr d\zeta = 2L \int n(\rho) 2\pi r dr
\]

if \( L \) is the half length of the cloud. By using the reduced parameter \( \rho \) and the definition of \( \lambda_D \), one can show that

\[
N / 2L = k_B T \epsilon_0 / q^2 \int \exp[\Psi(\rho)] 2\pi \rho d\rho.
\]

This number of ions depends implicitly on the central density \( n_0 \) through the parameter \( \gamma = n_c / n_0 - 1 \). Here, the

\[
\phi_T(r, z) = m / 2q \omega_T^2 r^2 + m / 2q \omega_L^2 z^2
\]
number of ions per unit length $N/2L$, the temperature $T$ and the central density $n_0$ are the three relevant parameters for the density profile problem and only two of them are free as they are related by equation (34).

- Second, to relate the two physical free parameters $N/2L$ and $T$ to the real size of the cloud, it is useful to note that, even if $\lambda_D$ does not appear explicitly in the differential equation, it is not a free parameter since

$$\frac{\lambda_D^2}{\gamma + 1} = \frac{k_B T}{2m\omega^2}. \tag{35}$$

As an experimentalist, one may want to know what the size of an ion cloud will be. The solution is there: for a given temperature $T$ and a given number of ions per unit length $(N/2L)$, $\gamma$ has to be found to fulfil the condition fixed by equation (34). Then $\lambda_D$ is deduced from equation (35) and the radial size of the cloud is given by $R = \lambda_D \rho_{\text{max}}$. The strength of the harmonic pseudopotential $\sqrt{m\omega^2}$ plays a role only in this scaling. It becomes necessary to know its value only when the size of the cloud is required. Examples of integrated radial profiles in the reduced and full scale coordinate are shown in figure 2 for the same number of ions per unit length and the same potential well $m\omega^2$ but for different temperatures. This figure illustrates the differences between a warm and dilute cloud where $\rho_{\text{max}} \approx 1$ ($T = 100000$ K, cases a and b) and a colder and denser cloud where $\rho_{\text{max}} \gg 1$ ($T = 5$ K, cases e and f), where the cold fluid model is relevant.

As mentioned above, theoretically, it is not appropriate to model warm and dilute samples by the cold fluid model, nevertheless, we can use the radial size calculated in this condition as an indication and compare it to the radius of the same sample cooled down. This is very important for experimental issues, as the actual number of laser-cooled trapped ions can be limited by the size it takes just after or during the ionization process. Indeed, when ions are created by electron bombardment, their initial temperature can reach an order of magnitude of 10000 K and comparison of plots (b, d, f) of figure 2 shows that the radial size of the same sample at 10000 K is nearly 4 times the size at 300 K and 6 times the one at 5 K. This illustrates one of the advantages of photoionization over electron bombardment to ionize a neutral beam. During the photoionization [32], the ions can be continuously loaded and laser cooled and the sample never reaches as high a temperature as by electron bombardment. Then the cloud remains smaller and more ions should be loaded in a trap, with less radiofrequency heating [33, 34].

For a laser-cooled non-neutral plasma $(N/2L \gg 10^3 \text{ mm}^{-1}, T \ll 1 \text{ K})$, or for a room temperature dense sample $(N/2L \gg 10^5 \text{ mm}^{-1}, T = 300 \text{ K})$, $\gamma$ is negligible in equation (35) which can be simplified to

$$\lambda_D^2 = \frac{k_B T}{2m\omega^2}. \tag{36}$$

This shows that in the cold fluid limit, for a given set $(T, N/2L)$, the size of a cylindrical cloud scales as $(m\omega^2)^{-1/2}$.

For temperatures close to the Doppler limit, the density profile of large enough sample $(\geq 10^3 \text{ ions mm}^{-1})$ is flat and expands to values of $\rho \gg 1$. We can then approximate the density profile by $\exp[\Psi(\rho)] = 1$ for $\rho \leq \rho_{\text{max}}$ and $\exp[\Psi(\rho)] \approx 0$ for $\rho > \rho_{\text{max}}$. The relation between the number of ions and the temperature is then simplified to

$$\frac{N}{2L} = \frac{k_B T \epsilon_0}{q^2 \pi \rho_{\text{max}}^2}. \tag{37}$$

As a consequence, the radial size $R$ of the cloud is given by

$$R = \sqrt{\frac{N}{2L} \sqrt{m\omega}} \sqrt{\frac{q^2}{2\pi \epsilon_0}}, \tag{38}$$

which is independent of the temperature and can be considered as the minimum limit radius $R_{\text{min}}$ for a sample. This limit for the size of a prolate cold cloud is equivalent to a maximum limit for the density

$$\frac{N}{\pi R^2 2L} \rightarrow 2m\omega^2 \epsilon_0 \frac{\rho_{\text{max}}^2}{q^2}, \tag{39}$$

which is of course the limit density $n_c$ we introduced at the beginning of the text.

To have an idea of this size, for a laser-cooled non-neutral plasma of Ca$^+$ in a linear quadrupole trap, the limit radius is given by the following relation when $\omega_x/2\pi$ is in MHz:

$$R = \sqrt{\frac{N}{2L} \frac{1}{\omega_x/2\pi}} \times 1.31 \times 10^{-8}. \tag{40}$$

Another issue concerns the phase transition to crystals. In finite size samples like that we deal with here, the transition from the liquid to the crystal state is not abrupt. Molecular dynamics simulations [12] and experiments [33] have shown that it takes place for values of the coupling parameter $\Gamma$ between 150 and 200. As the ions arrange themselves into concentric spheroidal shells, the diffusion inside a shell persists even for $\Gamma$ as big as 300 [12]. To study experimentally
such phase transitions in a finite system, it is then important to make sure that $\Gamma$ as high as a few hundred can be reached. For a laser-cooled dense sample, $\Gamma$ reaches a maximum limit $\Gamma_c$ depending on the limit density $n_c$. As an example, for calcium ions and for $\omega_x/2\pi$ in MHz,

$$\Gamma_c = \frac{g^2}{4\pi\varepsilon_0} \frac{(2m\omega_x^2)^{1/3}}{k_BT}.$$  

This relation shows that the maximum $\Gamma$ that can be reached in an experiment depends on the temperature of the sample, and the harmonic pseudopotential $m\omega_x^2$. As an example, for calcium ions and for $\omega_x/2\pi$ in MHz,

$$\Gamma_c = 4.8 \left(\frac{\omega_x/2\pi}{T}\right)^{2/3}.$$  

Several experiments [35, 36] with laser-cooled ions in linear radiofrequency traps have shown that because of heating processes such as radiofrequency heating, the Doppler limit is not reached with large samples and that an optimistic approach is to be made sure that $\phi(x)$ to be able to explore a wide range of $\Gamma$.

All the behaviour we have just described for a quadrupole linear trap cannot be extrapolated to multipole traps because the cold fluid limit does not result in a uniform density but rather in a profile density increasing with the radius. This relation shows that the maximum $\Gamma$ that can be reached in an experiment depends on the temperature of the sample, and the harmonic pseudopotential $m\omega_x^2$. As an example, for calcium ions and for $\omega_x/2\pi$ in MHz,

$$\Gamma_c = \frac{g^2}{4\pi\varepsilon_0} \frac{(2m\omega_x^2)^{1/3}}{k_BT}.$$

This relation shows that the maximum $\Gamma$ that can be reached in an experiment depends on the temperature of the sample, and the harmonic pseudopotential $m\omega_x^2$. As an example, for calcium ions and for $\omega_x/2\pi$ in MHz,
simulations [31]. Choosing the density in the centre of the trap $n_0$ as a reference for the density profile prevents one from finding an empty core but the high ratio between the maximum density and $n_0$ can be interpreted as a demonstration of this phenomenon. This effect increases with the order of the multipole as can be seen in figure 4 which shows a comparison between the density profile in a 8-pole and a 12-pole, for the same number of ions per length and the same trapping parameters. In the higher order geometry, the radial size of the cloud is 20% bigger than in the lower order geometry and the ratio of the maximum density over the central density is two times bigger.

For the validity of our cold fluid model, it is worth noting that, by analogy with the quadrupole case, we defined the Debye length $\lambda_D$ relative to the central density, which results in high values for $\lambda_D$ compared to the radial size of the cloud (see figure 3 for values). Nevertheless, the relevance of our model depends on the local Debye length $\lambda_D(\rho)$ compared to the size of the sample. We can see in figure 4 that, close to the edge of the cloud, this length $\lambda_D(\rho)$ is a lot smaller than $\lambda_D$, as the local density is far higher than $n_0$. Consequently, using the cold fluid model to scale such a cloud seems valid in the cold and dense limit.

As for a quadrupole, the cold fluid limit allows one to estimate the minimum size of a cloud by assuming the $T \rightarrow 0$ limit. To prevent divergence of the density at this limit, $\exp[\Psi(\rho)] - \alpha/\rho^{2k-4} \rightarrow 0$, with our previous notation. The maximum reduced radius visited by the ions is then determined by the linear density $N/2L$:

$$N/2L = k_B T e_0 \alpha \pi q^2 / k - 1 r_{\text{max}}^{2k-2}. \quad (47)$$

The dependence of the cold fluid limit radius $R_m$ on the trapping parameters can then be expressed as

$$R_m = r_0 \left( N/2L \pi e_0 (k-1) V_0 \right)^{1/(k-1)}. \quad (48)$$

To put values into this equation, let us choose the case of calcium ions in an octopole ($k = 4$) and express $\Omega/2\pi$ in MHz, then

$$R_m = \left[ N \left( \Omega/2\pi \right)^{1/6} \left( \Omega/2\pi \right)^{1/3} / V_0 \right] \times 0.45. \quad (49)$$

As an example, for $V_0 = 400 \text{ V}$, $\Omega/2\pi = 1 \text{ MHz}$ and $r_0 = 1 \text{ cm}$, the radial size of a cylindrical sample of $N/2L = 4.2 \times 10^4 \text{ ions mm}^{-1}$ is $R_m = 2.4 \text{ mm}$ in the cold fluid limit. As a comparison, at $300 \text{ K}$, the numerical integration gives $R = 3.8 \text{ mm}$.

Also like in quadrupole traps, the set of trapping parameters is constrained by stability criterion for the trajectories of the ions. But contrary to quadrupole traps, there is no absolute criterion but one can use the local adiabaticity criterion of Teloy and Gerlich introduced in section 2.1. For a perfect multipole like that we assume here,

$$\eta_{\text{ad}} = \left( k - 1 \right) q V_0 / (2 \kappa \varepsilon_k) r^{k-2}. \quad (50)$$

To be sure to remain in the adiabatic regime, we want to keep $\eta_{\text{ad}} \leq \eta_{\text{lim}}$ and then the radial size $R \leq r_{\text{max}}$ with

$$r_{\text{max}}^{k-1} = \eta_{\text{lim}} \left( 2 \kappa \varepsilon_k \right) / (k - 1) q V_0. \quad (51)$$

To have an idea of how this criterion is respected, it can be useful to compare, for a given set of trapping parameters, the smallest achievable radial size $R_m$ and the highest allowed radius for adiabatic trajectories $r_{\text{max}}$:

$$R_m / r_{\text{max}}^k = \left( N / 2L \right)^{1/(k-1)} \left( q / k \eta_{\text{lim}} \right)^{1/(k-2)} \times \left( k - 1 \right) \left( \kappa \varepsilon_k \right)^{k/(k-1)(k-2)} / (k - 1) q V_0. \quad (52)$$

For calcium ions in an octopole, this becomes

$$R_m / r_{\text{max}}^k = \left[ N / 2L \right] V_0 / \eta_{\text{lim}}(\kappa \varepsilon_k)^{1/(k-1)} \times 12.9. \quad (53)$$

As an example, for the same parameters as above ($V_0 = 400 \text{ V}$, $\Omega/2\pi = 1 \text{ MHz}$, $r_0 = 1 \text{ cm}$) and for the same number of ions per unit length $N/2L = 4.2 \times 10^4 \text{ ions mm}^{-1}$, $R_m / r_{\text{max}}^k = 0.75$ and the adiabaticity criterion is obeyed over all the cold sample (we used $\eta_{\text{lim}} = 0.3$ here).

By looking at equations (46), (48) and (52), one can note that if the ratio $\Omega / V_0$ is conserved, the absolute radial size is also conserved but not the ratio $R_m / r_{\text{max}}$. In practice, by substituting $\Omega / V_0$ by $2\Omega / V_0$, $R_m / r_{\text{max}}$ is reduced by a factor $\sqrt{2}$. One can use this difference in behaviour to scale ones trap and make sure that the desired sample fits inside the adiabatic volume.

4. Conclusion

In this paper, we have described the dynamics of charged particles in a radiofrequency trap in a very general manner to point out the differences between the dynamics in a quadrupole and in a multipole trap. When dense samples are trapped, the dynamics is modified by the Coulomb repulsion between ions.
To take into account this repulsion in the equilibrium state of the cloud, we use a method that models the ion cloud as a cold fluid. In the case of prolate clouds, it allows one to scale the size of the samples with the trapping parameters and the number of trapped ions, for different linear geometries of trap. We think this can be useful to build an experiment where a large number of ions needs to be trapped.
