Abstract: In this paper, we propose a strategy to solve endo-atmospheric launch vehicle optimal control problems using indirect methods. More specifically, we combine shooting methods with an adequate continuation algorithm, taking advantage of the knowledge of an analytical solution of a simpler problem. This procedure is resumed in two main steps. We first simplify the physical dynamics to obtain a new analytical guidance law which is used as initial guess for a shooting method. Then, a continuation procedure makes the problem converge to the complete dynamics leading to the optimal solution of the original system. Numerical results are presented.

Keywords: Optimal control, Real-time control, Continuation methods, Guidance of vehicles.

1. INTRODUCTION

Guidance of autonomous launch vehicles towards rendezvous points is a complex task often considered in missile applications, mainly for interception of targets. It represents an optimal control problem, whose aim consists in finding a control law enabling the vehicle to join a final point of the 3D space considering prescribed constraints as well as performance criteria. The rendezvous point may be a static point as well as a moving point if, for example, the task consists in intercepting a maneuvering target. This requires not only high numerical precision of concerned algorithms but also a real-time processing of optimal trajectories.

The most common approach to solve this kind of task resides on analytical guidance laws. They correct errors coming from perturbations and misreading of the system. However, the trajectories induced by guidance laws are not optimal because of some approximations made.

Ensuring the optimality of trajectories can be achieved exploiting direct methods. These techniques consist in discretizing each component of the optimal control problem (the state, the control, etc.) to reduce the whole mathematical representation to a nonlinear constrained optimization problem. Since they are quite robust, they are widely used [Hargraves and Paris, 1987], [Ross et al., 2003]. However, these methods are computationally demanding and can often be used offline uniquely.

In order to manage efficiently real-time processing of optimal control sequences for launch vehicle systems one may consider indirect methods. These use a mathematical study of the system (exploiting the Pontryagin Maximum Principle) to determine some necessary conditions of optimality. Indirect methods converge much faster than direct methods with a better precision. Since the problem is equivalent to the research of zeros of a function, the main difficulty remains their initialization. For example, in [Pan and Lu, 2010] the initialization problem is bypassed using finite differences algorithms and multiple-shooting methods respectively. However, these approaches remain computationally demanding and not easily applicable in view of real-time processing.

In this paper, we propose to solve endo-atmospheric launch vehicle optimal control problems using indirect methods managing the issue coming from the initialization by combining an analytical guidance law and a continuation method. Continuation procedures have shown to be reliable and robust for problems like atmospheric reentry and coplanar orbit transfer [Cerf et al., 2012], [Trélat, 2012]. This combination allows to preserve precision and fast numerical computations. The proposed approach is resumed in two main steps. We first simplify the physical dynamics to obtain a new analytical guidance law which is used as initial guess for a shooting method. Then, a continuation procedure makes the problem converge to the complete dynamics leading to the optimal solution of the original system.

The paper is structured as follows. Section 2 introduces the dynamics of a general endo-atmospheric launch vehicle system, the optimal control formulation and the related numerical approach. Section 3 is devoted to the construction of a simplified dynamics able to initialize successfully a shooting method. In Section 4 the continuation method that recovers the original dynamics is presented with some numerical tests. Finally, Section 5 contains conclusions and perspectives.
2. DYNAMICS, OPTIMAL CONTROL PROBLEM AND NUMERICAL METHOD

2.1 Physical Model

Let \((I, J, K)\) be an inertial frame centered at the center of the planet \(O\), \((e_2, e_1, e_3)\) be the NED frame and \((i, j, k)\) be the velocity frame. The endo-atmospheric launch vehicle system is modeled as an axisymmetric thrust propelled rigid body of mass \(m\). The coordinates \((r, l, L, v, \gamma, \chi) \in \mathbb{R}^6\) (\(L\) is the altitude, \(l\) is the longitude, \(\gamma\) is the path angle and \(\chi\) is the azimuth angle) are used to represent the position \(x = (r \cos(L), r \cos(L) \sin(l), r \sin(L))\) of the center of mass \(G\) of the vehicle and its velocity \(v = v \cos(\gamma) \cos(\chi) e_L + v \cos(\gamma) \sin(\chi) e_r - v \sin(\gamma) e_e\).

Neglecting the wind velocity, the Coriolis and the centripetal force (this is legitimate because of the short length of the considered trajectories), the dynamics takes the following form

\[
\begin{align*}
\dot{r} & = v \sin(\gamma), \quad L = \frac{v}{r} \cos(\gamma) \cos(\chi), \quad l = \frac{v}{r} \cos(\gamma) \sin(\chi) \\
\dot{v} & = \frac{f_T}{m} \cos(\alpha) - (d + \eta \sigma u^2) v^2 - g \sin(\gamma), \quad m = -q \\
\dot{\gamma} & = \frac{f_T}{m} \sin(\alpha) \cos(\beta) + \frac{v c_m u}{r} \sin(\beta) + \frac{v}{r} \cos(\gamma) \sin(\chi) \tan(L) \\
\dot{\chi} & = \frac{f_T}{m v} \cos(\gamma) \cos(\beta) + \frac{v c_m u}{r} \cos(\beta) + \frac{v}{r} \cos(\gamma) \sin(\chi) \tan(L)
\end{align*}
\]

where \(g\) is the modulus of the gravity, \(\eta\) is an aerodynamic efficiency coefficient, \(\alpha\) is the angle of attack and \(\beta\) is the angle of bank, \(u\) stands for the normalized lift coefficient while \(q = q(t)\) is the mass flow and \(f_T = f_T(t)\) represents the modulus of the thrust depending on \(q(t)\).

Based on a standard model of flight dynamics \([Pucci\ et\ al.,\ 2015]\, [Pepy\ and\ Hérissé,\ 2014]\), coefficients \(d\) and \(c_m\) are approximated by \(d = d(r) = \frac{1}{2m} \rho S \alpha_{\text{max}} D_d\) and \(c_m = c_m(r) = \frac{1}{2 \pi} \rho S \alpha_{\text{max}} C_d\) where \(S\) is the reference area, \(C_{\alpha_{\text{max}}}\) is the maximal value of the lift coefficient and \(C_d\) is the drag coefficient for \(\alpha = 0\), which is considered constant; finally, \(\rho\) is the air density for which an exponential model \(\rho = \rho_0 \exp(-(r - r_T)/h_v)\) is considered, where \(h_v\) is a reference altitude. Since \(q(t)\) is a predefined function of time, in this paper controls are only \(u\) and \(\beta\).

2.2 Optimal Control Problem and Maximum Principle

Consider now the Optimal Control Problem (OCP)

\[
\min \int_0^T f^0(t, x(t), u(t)) \, dt
\]

\[
\begin{align*}
\dot{x}(t) & = f(t, x(t), u(t)) \\
x(0) & = x_0 \in M_0, \quad x(t_f) = x_{tf} \in M_f
\end{align*}
\]

where \(x(t) = (r, L, l, v, \gamma, \chi) \in \mathbb{R}^6\), \(u(t) = (u, \beta)(t) \in \mathbb{R}^2\), \(f\) is the mapping defined by dynamics (1), \(M_0, M_f\) are smooth submanifolds of \(\mathbb{R}^6\) and the transfer time \(t_f\) is not fixed. Finally,

\[
f^0 = \sigma u^2 - \left(\frac{f_T}{m} \cos(\alpha) - (d + \eta \sigma u^2) v^2 - g \sin(\gamma)\right)
\]

where \(\sigma \geq 0\) is constant. By definition, \(u^2\) takes its values in \([0, 1]\). However, we do not consider any boundaries on \(u\) preferring to penalize it, using \(\sigma, \eta \sigma u^2\) within the cost.

The Pontryagin Maximum Principle (PMP) \([Boltyanskiy\ et\ al.,\ 1962]\) states that, if \(u\) is optimal with response defined on \([0, t_f]\), and shortly denoted \(x(t)\), then there exists \(p^0 \leq 0\) and \(p \in AC([0, t_f], \mathbb{R}^6)\) such that

\[
\dot{x} = \frac{\partial H}{\partial p}, \quad \dot{p} = -\frac{\partial H}{\partial x}, \quad H(t, x, p, u) = \max_{v \in U} H(t, x, p, v)
\]

\[
\max_{v \in U} H(t_f, x(t_f), p(t_f), v) = 0
\]

where \(H\) is the Hamiltonian and \(p\) satisfies the transversality conditions \(p(0) \perp T_{x(t_0)} M_0, \quad p(t_f) \perp T_{x(t_f)} M_f\). This is the content of the well known shooting method in optimal control \([Trélat,\ 2008]\, [Stoer\ and\ Bulirsch,\ 2013]\). Its advantage is its extremely good numerical accuracy, relevant for aerospace applications \([Trélat,\ 2012]\). Since it relies on the Newton method, it inherits of the very quick convergence properties of the Newton method. Its main drawback is that it may be difficult to initialize. To overcome this difficulty, one can entrust with the robustness of the continuation method. It consists in deforming the problem into a simpler one that we are able to solve and then in solving a series of shooting problems, step by step by parameter deformation, to recover the original problem \([Allgower\ and\ Georg,\ 2003]\). This approach increases the efficiency of the shooting method because it allows to relax its initialization. The continuation parameter \(\lambda\) may be a physical parameter (or several) of the problem, or an artificial one. The path consists of a convex combination of the simpler problem and of the original one.

The main algorithm proposed consists then in finding a solution of some simplification of (OCP) first and, from this, solving by continuation the original formulation (OCP).

3. NEW GUIDANCE LAW AS A GOOD ESTIMATE FOR THE CONTINUATION METHOD

Continuation methods allow us to solve iteratively (OCP) once the solution of some (usually) simpler optimal control problem is known. Here, we introduce and treat an efficient simpler problem coming from a modification of (1).

This modified version of (OCP) is designed with the hope that, on one hand, the shooting method can be easily
initialized and, on the other hand, the continuation is feasible. It is at this stage that intuition of aerospace engineer is of primary importance, in order to design simplified problems and homotopy parameters resulting in a meaningful continuation procedure.

### 3.1 Simplified Problem and Analytical Smooth Controls

If one ignores the contributions of the curvature of the Earth, of the gravity and of the thrust within (1), introducing the curvilinear abscissa \( s(t) := \int_0^t v(\tau) \, d\tau \) and a new variable \( w := \ln(v) \), the following simplification of (OCP) is obtained (the equation of \( w' \) can be neglected because it does not influence anymore the dynamics)

\[
\begin{align*}
\min & \int_0^t (d + \eta_{cm}(u_1^2 + u_2^2)) \, dt \\
\text{s.t.} & \quad r' = \sin(\gamma) \quad L' = \cos(\gamma)\cos(\chi) \\
& \quad \gamma' = \frac{c_{uw}}{\cos(\gamma)} \quad \chi' = \frac{c_{uw}^2}{\cos(\gamma)}
\end{align*}
\]

(7)

where \( u_1 := u \cos(\beta) \), \( u_2 := u \sin(\beta) \) and with initial, final conditions \((r_0, L_0, \theta_0, \alpha_0)\), \((r_f, L_f, \theta_f, \alpha_f)\).

The next step consists in finding an analytical solution of (7). This is achieved exploiting the PMP formulation, as showed in the following.

The associated Hamiltonian function is

\[
H = p_r \sin(\gamma) + p_\chi \cos(\gamma)\cos(\chi) + p_l \cos(\gamma)\sin(\chi) + \frac{r}{r \cos(L)}
\]

(8)

It can be remarked that, since the transfer time is not fixed and formulation (7) is autonomous, (8) takes zero as value for all times \( t \in [0, t_f] \). Since no constraints are considered on \( u_1, u_2 \), from applying the weaker version of PMP, it follows explicitly that

\[
p_r = -2\eta_{cm}^0 u_1 \quad p_\chi = -2\eta_{cm}^0 \cos(\gamma) u_2
\]

(9)

Simple calculations show that

\[
\begin{align*}
p_r' &= -p_r \cos(\gamma)\cos(\chi) + p_\chi \cos(\gamma) \sin(\omega) + \frac{p_l}{r} - \eta_{cm}(u_1^2 + u_2^2) \\
p_L' &= -p_r \cos(\gamma)\cos(\chi) + p_\chi \cos(\gamma) \sin(\chi) - \frac{p_l}{r} \cos(L) \\
p_\chi' &= -p_r \cos(\gamma)\cos(\omega) + p_\chi \cos(\gamma) \sin(\omega) + p_l \cos(\gamma) \sin(\chi) - \frac{p_l}{r} \sin(L)
\end{align*}
\]

(10)

It is clear that, if additional assumptions allow to neglect the contribution of \( P_1(u_1, u_2, u_1', u_2') \), \( P_2(u_1, u_2, u_1', u_2') \), the equations of system (11) can be solved independently of \( u_1, u_2 \) of their first derivatives. Since \( \frac{1}{2} \) the previous expression can be approximated. Iterating the same procedure on \( u_2 \) one is led to solve

\[
\begin{align*}
u_1' &= \frac{c_{uw}}{2\eta} \left( u_1 + \frac{\cos(\gamma)}{c_{uw}} \right) + P_1(u_1, u_2, u_1', u_2') \\
u_2' &= \frac{c_{uw}}{2\eta} u_2 + P_2(u_1, u_2, u_1', u_2')
\end{align*}
\]

(11)

where \( P_1(u_1, u_2, u_1', u_2') \) is a polynomial of degree greater than one of \( u_1, u_2 \) and their first derivatives. Since \( \frac{1}{2} \) the previous expression can be approximated. Iterating the same procedure on \( u_2 \) one is led to solve

\[
\begin{align*}
u_1' &= \frac{c_{uw}}{2\eta} \left( u_1 + \frac{\cos(\gamma)}{c_{uw}} \right) + P_1(u_1, u_2, u_1', u_2') \\
u_2' &= \frac{c_{uw}}{2\eta} u_2 + P_2(u_1, u_2, u_1', u_2')
\end{align*}
\]

(11)

This result allows to solve (11) removing the contributions of \( P_1(u_1, u_2, u_1', u_2') \) and \( P_2(u_1, u_2, u_1', u_2') \).

Anyway, initial conditions for controls and their first derivatives must be sought. Two conditions are given using the two last equations of (7). The initial conditions of the derivatives can be investigated exploiting an analysis of the Line Of Sight (LOS).

### 3.2 LOS and New Approximated Analytical Guidance Law

The line of sight is the vector joining the current position \( \xi \) to the desired final point \( \xi_f \). It results to be useful defining its modulus \( R := ||\xi_f - \xi|| \) and the associated unitary vector \( \mathbf{n} := \frac{\xi_f - \xi}{||\xi_f - \xi||} \).

We denote \( (i_n, j_n, k_n) \) the orthonormal frame where \( i_n = \mathbf{n}, j_n \) is the unitary vector in the plane \((i_n, e_i)\) perpendicular to \( i_n \) and oriented by \( j_n \), \( e_i < 0 \) and \( k_n = i_n \wedge j_n \). Frames \((i, j, k)\), \((i_n, j_n, k_n)\) are functions of \((e_{i_L}, e_{i_V}, e_{i_R})\) by definition, locally according to
Then, since under the usual assumption \( \dot{\lambda} \)
using (14) and noticing that \( \lambda \)
\( \dot{\lambda} = 0 \), \( \dot{\lambda} = \sin(\gamma) \cos(\chi) e_L + \cos(\gamma) \sin(\chi) e_t - \sin(\gamma) e_r \),
\( \dot{j} = -\sin(\gamma) \cos(\chi) e_L - \sin(\gamma) \sin(\chi) e_t - \cos(\gamma) e_r \),
\( \dot{k} = -\sin(\chi) e_L + \cos(\chi) e_t \),
\( i_n = \cos(\lambda_2) \sin(\chi) e_L + \cos(\lambda_2) \cos(\chi) e_t - \sin(\lambda_2) e_t - \sin(\lambda_2) e_t - \cos(\lambda_2) e_r \),
\( k_n = -\sin(\lambda_2) e_L + \cos(\lambda_2) e_t \)
where \( \lambda_1, \lambda_2 \) are Euler angles. The coordinates of a vector within a frame \((a, b, c)\) are denoted as \(\langle \gamma \rangle_{(a, b, c)}\).

First-Order Approximation 1. (FOA). Along the considered trajectories, only weak variations from the LOS direction are allowed, i.e. \( \gamma \cong \lambda_1, \chi \cong \lambda_2 \). Moreover, the contribution of the rotation of frame \((e_L, e_t, e_r)\) around frame \((I,J,K)\) is neglected, i.e. \(\dot{\gamma}^2(n)_{(e_L, e_t, e_r)} \cong \dot{\theta}^2(n)_{(e_L, e_t, e_r)}\).

Initial conditions of the derivatives of controls \(u_1, u_2\) are obtained considering (FOA). Indeed, this assumption allows to recover \(u_1, u_2\) as analytical guidance laws which generalize the one presented in [Lin, 1991]. It must be remarked that (FOA) is not a strong assumption because the initial scenario involved lives in a neighborhood of the null control and the considered trajectories are short enough to make this choice effective.

First of all, we recall the following (see [Bonalli et al., 2017])

Lemma 1. Under (FOA), the following relations hold
\[
\dot{\lambda}_1 = -\frac{v}{R} \sin(\gamma - \lambda_1), \quad \dot{\lambda}_2 = -\frac{v}{R} \sin(\chi - \lambda_2)
\]  

Lemma 1 is used as follows. We impose \(c_m, d \) and \(\cos(\gamma)\) to be constant along the trajectory (thanks to considerations of Section 3.1). We start considering control \(u_1\). From (11),
\[
u_1(s) = \frac{c_m v}{\lambda_1} + \frac{b}{c_m} \left( e^{bR} - 1 \right) - \frac{c_m v}{\lambda_1} \frac{\cos(\gamma)}{R} R
\]
Plugging (13) into equation \(\gamma' = c_m u_1\) and integrating,
\[
\gamma - \gamma(R) = \frac{A c_m}{b} \left( e^{bR} - 1 \right) - \frac{B c_m}{b} \left( e^{bR} - 1 \right) - \frac{\cos(\gamma)}{R} R
\]
Thanks to (FOA), one has \(\dot{R} = -v \cos(\gamma - \lambda_1)\). Now, (12) is used to differentiate the quantity \(R \sin(\gamma - \lambda_1)\). Indeed
\[
\frac{d}{dt} \left( R \sin(\gamma - \lambda_1) \right) = R \sin(\gamma - \lambda_1) + R \cos(\gamma - \lambda_1) \gamma - \lambda_1 - R \cos(\gamma - \lambda_1) \lambda_1 + v \sin(\gamma - \lambda_1) \cos(\gamma - \lambda_1)
\]
\[
= R \cos(\gamma - \lambda_1) \gamma_1 + R \cos(\gamma - \lambda_1) \gamma_1 + v \sin(\gamma - \lambda_1) \cos(\gamma - \lambda_1)
\]
\[
= R \cos(\gamma - \lambda_1) \gamma_1 + R \cos(\gamma - \lambda_1) \gamma_1 + R \cos(\gamma - \lambda_1) \gamma_1 + R \cos(\gamma - \lambda_1) \gamma_1 = -R c_m u_1
\]
Then, since under the usual assumption \(\dot{R} \cong \dot{v}\), it follows \(R \sin(\gamma - \lambda_1) = R c_m u_1\). Integrating this last equation, using (14) and noticing that \(R(s) = 0\), one has
\[
k_1(R) = \frac{b R e^{bR} - e^{-bR} - 2 b R}{4 e^{bR} (b R - 2) - e^{-bR} (b R + 2)}
\]
\[
k_2(R) = \frac{b R e^{bR} (b R - 2)}{4 e^{bR} (b R - 2) - e^{-bR} (b R + 2)}
\]
Since \(\sin(\gamma - \lambda_1) \cong \gamma - \lambda_1\), the following guidance law for control \(u_1\) is deduced
\[
u_1(R) = -k_1(R) \gamma - \lambda_1(R) - k_2(R) \sin(\gamma - \lambda_1(R)) \]
(15)

where \(k_3(R) = 2 + k_1(R) - k_1(R)\).

With the same argumentation, exploiting again (12), the following guidance law for control \(u_2\) can be easily derived
\[
u_2(R) = -\cos(\gamma(R)) k_1(R) \gamma - \lambda_1(R) + k_2(R) \sin(\gamma(R) - \lambda_2(R)) \]
(16)

As suggested before, relations (15), (16) provide an analytical guess for \(\gamma, f, p_\gamma (0), p_\lambda (0), p_\beta (0), p_\gamma (0)\) to initialize the shooting method applied to problem (7). Indeed, they may be chosen as \(\gamma(R) = 0\), \(p_\gamma (0) = 2 \mu (1)\), \(p_\lambda (0) = 2 \eta \cos(\gamma(R)) u_2(0)\) and the guess values of \(p_\beta (0), p_\gamma (0), p_\lambda (0)\) are obtained from (8) and (10).

4. RECOVER THE SOLUTION OF THE ORIGINAL SYSTEM BY A CONTINUATION METHOD

Since the procedure developed in Section 3 gives us a good guess to initialize the shooting method on a simplified version of (OCP), we proceed now to the analysis of the continuation method that allows to recover an optimal solution of (OCP) starting an homotopy procedure on the simplified problem (7).

Clearly, several types of different continuations can be implemented. However, we verified that passing from (7) to (OCP) through a continuation parameter \(\lambda_1\) and, after that, changing the final point of the initial scenario directly on (OCP) with another parameter \(\lambda_2\) results to be convenient to obtain a fast convergence to the optimal solution.

4.1 Solution of the Original Problem

Without loss of generality, we focus on a particular instance of (OCP), whose cost (see (3)) takes the form
\[
f^0(t, x(t), u(t)) = -\left( \frac{f R}{m} \cos(\alpha) - (d + n \eta m u^2)^2 - g \sin(\gamma) \right)
\]
The system, which depends on \(\lambda_1\), is introduced exploiting the change of variable \(w := \ln(v)\) that leaves the formulation consistent with the simplified model (7) as it is shown hereafter. If we denote \(x_f\) the final point of the initial test scenario (see Section 3.1) and \(x_f\) the final point of the desired scenario, we have
\[
\min \int_0^{t_f} \left[ \lambda_1 \left( \frac{f R}{m \eta} \cos(\alpha) - \frac{g}{2 \sin(\gamma)} \right) - (d + n \eta m u^2)^2 \right] \]  
\[
\gamma = \frac{f R}{m \eta} \cos(\alpha) - \frac{g}{2 \sin(\gamma)} \left( \frac{f R}{m \eta} \cos(\alpha) - \frac{g}{2 \sin(\gamma)} \right)
\]
\[
\xi = \frac{f R}{m \eta} \cos(\alpha) + \frac{g}{2 \sin(\gamma)} \tan(L) + \frac{f R}{m \eta} \sin(\alpha) \sin(\beta)
\]
(17)
where the final point takes the form \( \mathbf{x}(t_f) = \mathbf{x}_f + \lambda_2 (\mathbf{x}_f - \mathbf{x}_0) \), \((\lambda_1, \lambda_2) \in [0,1]^2\) and the evolution of the mass is given by \( m(t) = m_0 - \lambda_1 \int_0^t \dot{q}(s) \, ds \). The continuation algorithm implemented makes \((\lambda_1, \lambda_2)\) converge from \((0,0)\) to \((1,1)\).

As usual, the Hamiltonian of (17) takes the form \( H = (p, f) + p^0 \) where we assume that \( p^0 \neq 0 \) (which is coherent with the simplified formulation (7)). A priori, the Hamiltonian is not uniformly equal to zero because \( f_T = f_T(t), q = q(t) \) depend explicitly on \( t \). From transversality conditions we obtain

\[ p_u(t_f) = 0 \]  

Finally, since no constraints are considered on controls \( \beta, u \), relations \( \frac{\partial H}{\partial \beta} = 0 \) and \( \frac{\partial H}{\partial u} = 0 \) hold. From the first one we have

\[ 0 = p_c \cos w u \cos(\beta) + p_t \cos w u \sin(\beta) + p_u \sin(\alpha) \cos(\gamma) - p_v \sin(\alpha) \sin(\beta) \]  

An analytical formulation of \( \beta \) is immediately obtained if a first-order approximation \( \cos(\alpha) \approx 1, \sin(\alpha) \approx \alpha \) is considered (this remains proper if small values of \( \alpha_{\text{max}} \) are considered). Indeed, from (19) it follows

\[ p \frac{\cos(\beta)}{\cos(\gamma)} - p_u \sin(\beta) = 0 \]  

The associated optimal values recovered by the proposed approach are (in standard units) \((v(t_f), t_f)_{S_1} = (896.7, 24.5), (v(t_f), t_f)_{S_2} = (851.6, 36.6)\) and \((v(t_f), t_f)_{S_3} = (688.8, 31.5)\). Using around 400 time steps within the explicit second-order Runge-Kutta solver for the integration of the ODEs inside the shooting function, the simulations take on average 0.27 s for \( S_1 \), 0.73 s for \( S_2 \) and 2.1 s for \( S_3 \). These computing times remain in the order of 1 Hz giving the possibility to consider the whole procedure as an efficient real-time processing.

The previous approach was treated also with a non-initialized direct method (AMPL/IPOPT with 200 time steps) [Fouyer et al., 1993]. Modifying the boundaries and the initial guess of IPOPT, the three scenarios are solved by the direct method (obtaining the same optimal solutions provided previously) with computational times that vary respectively between 1 s and 2 s for \( S_1 \), 2 s and 5 s for \( S_2 \), 5 s and 10 s for \( S_3 \). Our indirect approach reveals itself to be at least as efficient as a direct method, and sometimes more successful.

It is interesting to note that scenarios \( S_1, S_2 \) do not require step 3 of the previous algorithm to be solved: imposing \( \mathbf{x}_f := \mathbf{x}_f \) within step 1, the initial guess is good enough to find the solution of \((\text{OCP})\) with a continuation on \( \lambda_1 \) only. From this, 3 iterations of the continuation method on \( \lambda_1 \) are required to solve \( S_1 \), 10 iterations on \( \lambda_1 \) for \( S_2 \) while 18 iterations on \( \lambda_1 \) and 6 iterations on \( \lambda_2 \) are needed to solve \( S_3 \).

The trajectories and the optimal controls \( u_1 := u \cos(\beta), u_2 := u \sin(\beta) \) are shown in Figure 1. It is interesting to note that, even if no explicit constraint are considered on both the controls, they turn out to be bounded in \([-1,1]\).

They are forced to be small due to the presence of \( u^2 \) inside the cost function.

### 5. CONCLUSIONS AND PERSPECTIVES

In this paper we solve an optimal control problem for endo-atmospheric launch vehicle systems using indirect methods. The problem is solved mixing an analytical initialization with a continuation method on the dynamics. First, a
simplified version of the original problem is solved. Then, a continuation method which recovers the complete optimal solution starts: every shooting method within the iterative procedure is initialized by the approximate solution found at the previous stage. This approach provides numerical precision and high computational. Moreover, numerical simulations show that this approach may compete with usual direct methods.

Clearly, some improvements can be brought. A first remark concerns the model. Indeed, the velocity of the wind and stabilizing components within the cost such as $\sigma u^2$ have not been considered in the previous analysis. However, such terms can be added to the formulation exploiting a new stage of continuation on them. Secondly, in this contribution, neither control constraints nor state constraints were taken into account. It is not hard to consider control constraints (a detailed geometric study [Bonalli et al., Possibly 2017] shows that neither abnormal nor singular arcs exist for this problem) while state constraints result to be more challenging (one could, for example, penalize these constraints within the cost function [Zhu et al., 2016]). Finally, as in previous sections, dynamics (1) reveals some singularities due to eulerian coordinates. In order to deal with this flaw, an inline change of coordinates can be considered during the numerical procedure. This strategy does not increase the computational effort and it allows to solve more scenarios [Bonalli et al., Possibly 2017]. All these precious improvements will be reported in [Bonalli et al., Possibly 2017].
