ABSTRACT

We combine recent estimates of dust extinction at \( z \sim 4–7 \) with UV luminosity function (LF) determinations to derive star formation rate (SFR) functions at \( z \sim 4–7 \). SFR functions provide a more physical description of galaxy buildup at high redshift and allow for direct comparisons to SFRs at lower redshifts determined by a variety of techniques. Our SFR functions are derived from well-established \( z \sim 4–7 \) UV LFs, UV-continuum slope trends with redshift and luminosity, and infrared excess (IRX)–\( \beta \) relations. They are well described by Schechter relations. We extend the comparison baseline for SFR functions to \( z \sim 2 \) by considering recent determinations of the H\( \alpha \) and mid-IR LFs. The low-end slopes of the SFR functions are flatter than for the UV LFs, UV-continuum slope trends with cosmic time (\( z \sim 0–7 \)). In addition, we find that the characteristic value SFR\(^* \) from the Schechter fit to the SFR function exhibits consistent, and substantial, linear growth as a function of redshift from \( \sim 5 \, M_\odot \, yr^{-1} \) at \( z \sim 8, 650 \) Myr after the big bang, to \( \sim 100 \, M_\odot \, yr^{-1} \) at \( z \sim 2, \sim 2.5 \) Gyr later. Recent results at \( z \sim 10 \), close to the onset of galaxy formation, are consistent with this trend. The uniformity of this evolution is even greater than seen in the UV LF over the redshift range \( z \sim 2–8 \), providing validation for our dust corrections. These results provide strong evidence that galaxies build up uniformly over the first 3 Gyr of cosmic time.

Key words: galaxies: evolution – galaxies: high-redshift

1. INTRODUCTION

In recent years great progress has been made in determining the UV luminosity function (LF) at early times (e.g., Steidel et al. 1999; Wyder et al. 2005; Arnouts et al. 2005; Reddy & Steidel 2009; Bouwens et al. 2007, 2011b; Oesch et al. 2010, 2012b). Recent results on the UV LF indicate a bright end that builds up substantially with time, with the characteristic luminosity increasing from the highest redshifts to \( z \sim 3–4 \) (e.g., Bouwens et al. 2007). Furthermore, the faint-end slope of the UV LF is found to be very steep at redshifts \( z \geq 3 \) (e.g., Bouwens et al. 2011b). This brightening of \( L_{UV}^* \) and steep faint-end slope \( \alpha \) are consistent with a general picture where galaxies build up hierarchically and where lower luminosity galaxies play a major role in the reionization of the universe.

Despite the general usefulness of the UV LF for probing early galaxy formation, one significant limitation of the UV LF in this regard is the sensitivity of rest-frame UV light to dust extinction. Inferring this attenuation directly at \( z > 3 \) is challenging since only the most bolometrically luminous systems at these redshifts can be detected in far-IR. Also, for these very high redshifts, tracers of star formation such as X-ray, radio, 24 \( \mu \)m, and H\( \alpha \) are either too faint to observe or redshifted out of the observable wavelength range of the most sensitive telescopes.

Fortunately, we can take advantage of a relation between the UV-continuum slope \( \beta \), with \( f_\beta \propto \lambda^\beta \) (Meurer et al. 1999), and the likely dust extinction to convert the observed UV luminosities into star formation rates (SFRs; see, e.g., Bouwens et al. 2009). It has only now been possible to accurately establish the distribution of the UV-continuum slope distribution over a wide range in luminosity and redshift (e.g., Bouwens et al. 2009, 2012; Wilkins et al. 2011; Finkelstein et al. 2012; Castellano et al. 2012; Dunlop et al. 2012). This is the result of the installation of the WFC3/IR camera on the Hubble Space Telescope and the recent acquisition of deep wide-area data over the HUDF09+CANDELS fields (Bouwens et al. 2012; Grogan et al. 2011; Koekemoer et al. 2011).

In this paper, we utilize these new UV-continuum slope determinations to derive SFR functions at \( z \sim 4–7 \). SFR functions can better connect the growth of galaxies at the highest redshifts to galaxies found at later epochs, as well as give insight into the manner in which star formation lights up dark matter halos. Previously, such functions were presented at \( z \sim 0–1 \) based on UV+IR data (Martin et al. 2005; Bell et al. 2007; Bothwell et al. 2011). We begin this paper by describing how we use \( \beta \) to produce dust-corrected UV LFs and SFR functions (Section 2). In Section 3 we compare our SFR functions with the literature over a range of redshifts (\( z \sim 0–8 \)). For ease of comparison with previous studies we adopt \( H_0 = 70 \, km \, s^{-1} \, Mpc^{-1} \), \( \Omega_m = 0.3 \), and \( \Omega_L = 0.7 \). We adopt a Salpeter (1955) initial mass function (IMF) with limits 0.1–125 \( M_\odot \) throughout this paper.

2. SFR FUNCTIONS

This section describes how we compute SFR functions from published UV LFs and UV-continuum slopes \( \beta \). We begin by deriving the SFR functions in a fully stepwise fashion, applying our luminosity-dependent dust corrections to binned UV LFs (Section 2.1). We then derive analytical formulae for these SFR functions based on the UV LFs we use as inputs (Section 2.2).
2.1. Dust-corrected Luminosity Functions

We correct UV LFs for the effects of dust attenuation using the well-known correlation of extinction with the UV-continuum slope $\beta$. We take the infrared excess (IRX)–$\beta$ relation established by Meurer et al. (1999),

$$A_{1600} = 4.43 + 1.99 \beta. \quad (1)$$

Meurer et al. (1999) estimated the relation based on starburst galaxies in the local universe. Similar relations have been found at $z \sim 0$ by other groups (Burgarella et al. 2005; Overzier et al. 2011). Though there is some evidence that the Meurer et al. (1999) relation does not work well for all sources, e.g., very young galaxies ($<100$ Myr) and ultraluminous infrared galaxies (ULIRGs; e.g., Reddy et al. 2006), this relation has been found to be accurate in the mean out to $z \sim 2$, despite considerable scatter (e.g., Daddi et al. 2007; Reddy et al. 2006, 2010, 2012; Magdis et al. 2010a, 2010b). There is even evidence in the new Herschel observations that the Meurer et al. (1999) relation is reasonably accurate in estimating the dust extinction for $z \sim 2$ Lyman break galaxies (LBGs; Reddy et al. 2012). We therefore quite reasonably utilize this relation in interpreting higher redshift samples.

Recently there have been a number of studies examining $\beta$ in high-redshift samples (e.g., Bouwens et al. 2009, 2012; Wilkins et al. 2011; Finkelstein et al. 2012; Dunlop et al. 2012). Perhaps the most definitive of these studies is Bouwens et al. (2012), who, using the CANDELS+HUDF09 data sets, find that $\beta$ correlates with both redshift and luminosity, with higher redshift and lower luminosity galaxies being bluer. The results by Bouwens et al. (2012) are in excellent agreement with other results in the literature (e.g., Ouchi et al. 2004; Labbé et al. 2007; Overzier et al. 2008; Wilkins et al. 2011).

For our dust corrections we assume a linear relation between the UV-continuum slope $\beta$ and luminosity, such as that given in Bouwens et al. (2012). This is shown in the top panel of Figure 1 for $z \sim 4$,

$$\langle \beta \rangle = \frac{d\beta}{dM_{\text{UV}}} (M_{\text{UV,AB}} + 19.5) + \beta_{M_{\text{UV}}=-19.5}. \quad (2)$$

where $d\beta/dM_{\text{UV}}$ and $\beta_{M_{\text{UV}}=-19.5}$ are from Table 5 of Bouwens et al. (2012). Note that for $z \sim 7$ we use a fit with a fixed slope $d\beta/dM_{\text{UV}} = -0.13$ obtained from our $z \sim 4$–6 samples, given the large uncertainties in this slope at $z \sim 7$ and the lack of evidence for evolution in the $\beta$–luminosity relation over the redshift range $z \sim 2$–6. The distribution of the UV-continuum slope $\beta$ shows substantial scatter about relation (2), that can be approximated by a normal distribution (Figure 1; but note that there is a fatter tail toward redder $\beta$).

The steps for computing an average dust correction are as follows. We use Equation (1) to calculate the UV absorption $A_{1600}$ for each source in our adopted $\beta$-distribution. Then to obtain the extinction correction at a given $M_{\text{UV}}$, we integrate over the $\beta$-distribution (normal distribution with mean $\langle \beta \rangle$, Equation (2), and $\sigma_{\beta} = 0.34$), setting $A_{1600} = 0$ when $A_{1600} < 0$. The middle panel of Figure 1 shows the resulting $A_{M_{\text{UV}}}$ as a function of luminosity at $z \sim 4$. We then apply this dust correction to the UV luminosities of individual bins of the LF. We shift each point in the LF toward brighter magnitudes and correct for the fact that the luminosity-dependent dust correction increases the width of the bins.

The bottom panel of Figure 1 shows the effect of our luminosity-dependent dust correction on the stepwise UV LF at $z \sim 4$ from Bouwens et al. (2007). The dust correction shifts the LF to higher luminosities, particularly at the bright end, causing $M_{\text{UV}}^* \sim 20$ to brighten, and also flattens the faint-end slope. There is also a small shift to lower volume densities due to the renormalization of the magnitude bins.

Now that we have dust-corrected UV fluxes we can use well-established relations to compute the SFR as a function of luminosity, giving us our desired SFR functions. We use the following relation from Kennicut (1998):

$$\frac{\text{SFR}}{M_\odot \text{yr}^{-1}} = 1.25 \times 10^{-28} \frac{L_{\text{UV,corr}}}{\text{erg s}^{-1} \text{Hz}^{-1}}. \quad (3)$$

Since this relation gives the time-averaged SFR over a $\sim 100$ Myr time window, it will underestimate the SFR (typically by $\lesssim 2 \times$) in galaxies substantially younger than this (e.g., Verma et al. 2007; Bouwens et al. 2012; Reddy et al. 2012). However, Equation (3) should work on average for the extended star formation histories expected in LBGs.

The left panel of Figure 2 shows the stepwise SFR functions at $z \sim 4$–7, based on stepwise UV LFs derived from Bouwens et al. (2012); the inset panel shows the luminosity de-trended distribution of UV-continuum slopes around the mean relation. Middle: the average dust extinction from the $\beta$-distribution in the upper panel as a function of luminosity, assuming a Meurer et al. (1999) dust correction, as described in Section 2.1. The error bar in the bottom left corner shows both the random and systematic uncertainties in the relation. Bottom: the black and red points show the $z \sim 4$ UV LF from Bouwens et al. (2007) before and after correction for dust (see Section 2.1). The error bar in the top left corner shows the fiducial error in the average dust correction. The dust-corrected UV LF has a flatter faint-end slope $\alpha$ and brighter $M_{\text{UV}}^*$.

(A color version of this figure is available in the online journal.)
et al. (2007, 2011b). For convenience, we include our stepwise SFR functions in Table 1.

2.2. Analytical SFR Functions

In this section, we use an analytical Schechter-like approximation to represent SFR functions at $z \sim 4$–7.

We assume that the IRX–$\beta$ relation for individual galaxies is described by $A_{UV} = C_0 + C_1 \beta$ and the distribution of galaxies at a certain $M_{UV}$ is given by a Gaussian with $\mu_{\beta} = \langle \beta \rangle$ (Equation (2)) and width $\sigma_{\beta}$, which gives

$$\langle A_{M_{UV}} \rangle = C_0 + 0.2 \ln 10 C_1^2 \sigma_{\beta}^2 + C_1 \langle \beta \rangle. \tag{4}$$

This expression is only valid in the limit that the distribution of UV-continuum slopes $\beta$ does not extend to $\beta \lesssim -2.3$ since such blue $\beta$ formally give negative dust corrections (a clearly non-physical result) using the Meurer et al. (1999) relation. For the Meurer et al. (1999) relation Equation (4) simplifies to

$$\langle A_{M_{UV}} \rangle = 4.43 + 1.82 \sigma_{\beta}^2 + 1.99 \langle \beta \rangle. \tag{4}$$

To compute SFR functions we start with the UV LF, described in Schechter form (Schechter 1976):

$$\phi(L) dL = \phi^*(L/L^*)^\alpha \exp\left(-\frac{L}{L^*}\right) \frac{dL}{L^*}. \tag{5}$$

Substituting SFR for $L$ (and $SFR^*$ for $L^*$), using Equations (2)–(4) yields

$$\phi(SFR) dSFR = \frac{\phi^*(SFR/SFR^*)^{\alpha C_1 \frac{dSFR}{dM} \sigma_{SFR}}}{1 - C_1 \frac{dSFR}{dM} \sigma_{SFR}} dSFR. \tag{6}$$

where we have made the simplifying assumption that the cutoff in the Schechter function is exponential and not some slightly shallower high-end cutoff (the modified functional form is consistent with the observations). This gives the conversions

$$\alpha_{SFR} = \frac{\alpha_{UV,uncorr} + C_1 \frac{dSFR}{dM}}{1 - C_1 \frac{dSFR}{dM}. \tag{7}$$

$$\phi_{SFR}^{*} = \phi_{UV,uncorr}^{*} \left(1 - C_1 \frac{dSFR}{dM}\right). \tag{8}$$

We calculate $SFR^*$ using Equations (2)–(4), i.e., we use \log_{10} SFR$^*= -0.4 (M_{UV,uncorr} A_{M_{UV}} - 7.25$. Though Equation (4) is a reasonable approximation for $A_{M_{UV}}$, our estimate of $SFR^*$ is slightly more accurate when we estimate $A_{M_{UV}}$ as described in Section 2.1, by setting $A_{1600} = 0$ when $A_{1600} < 0$. Therefore, we will use this more accurate estimate of SFR$^*$ quoted in Table 2.

The left panel of Figure 2 compares the analytical SFR functions (solid lines) with the corrected stepwise UV LFs described in Section 2.1. They are in excellent agreement, providing a useful check on the analytic description used here. We would expect our derived SFR functions to be more uncertain at high bolometric luminosities ($L_{bol} > 10^{12} L_\odot$; indicated in Figure 2), where dust corrections are likely less reliable (e.g., Reddy et al. 2006) and our Lyman break selections may be more incomplete to dusty star-forming galaxies (e.g., Daddi et al. 2009; Michalowski et al. 2010). While this should not affect the turnover in the SFR function, the SFR function may fall off less steeply than the exponential form adopted here.

The analytical Schechter parameters are presented in Table 2. The SFR$^*$, $\phi_{SFR}^*$, and $\alpha_{SFR}$ are calculated assuming the $z \sim 4$–7 UV LF parameters from Bouwens et al. (2007, 2011b), the $dSFR/dM$, $\beta_{M_{UV}=19.5}$, and $\sigma_{\beta}$ = 0.34 from Bouwens et al. (2012).
and the Meurer et al. (1999) relation (Equation (1)). For the $z \sim 7$ LF parameters, we modify our procedure somewhat due to the fact that Equation (4) is not especially accurate for the very blue $\beta$ found at $z \sim 7$ (see discussion following Equation (4)). Specifically, we keep the SFR* fixed to the value described above and then fit the low-end slope and the normalization of the Schechter function to the stepwise UV LF.

We have verified through Monte Carlo simulations that we can successfully recover $(\Delta M^* \lesssim 0.13 \text{ mag}, \Delta \alpha \lesssim 0.03)$ the observed UV LFs and $\beta$–luminosity relation using the derived SFR functions and a $\beta$–SFR relation (e.g., Castellano et al. 2012), so our approach can be inverted. We describe these simulations in detail in the Appendix.

We remark that if $\beta$ shows a weaker dependence on luminosity than Bouwens et al. (2012) find (e.g., Castellano et al. 2012; Dunlop et al. 2012) it would result in a steeper $\alpha_{\text{SFR}}$ and higher $\phi_{\text{SFR}}$ ($\Delta \phi_{\text{SFR}} \sim 0.05 \text{ dex}$). Uncertainties in both the incompleteness and contamination corrections used for the UV

3. RESULTS

One of the main results of this paper is our determination of the approximate Schechter parameters for the SFR function. These parameters allow for an intuitive and quantitative look at how this function evolves with cosmic time, as well as allowing for a comparison with lower redshift determinations. We discuss both the high-SFR and low-SFR end of the SFR function.

3.1. High-SFR End: Linear Buildup of log SFR* from \(z \sim 8\) to \(z \sim 2\)

The high-SFR end of the SFR function is interesting since it provides us with a direct measure of the rate at which luminous galaxies are building up at early times. We compare our parameters with various studies that combine UV and IR observations to obtain complete SFR functions at \(z \lesssim 2\), i.e., Bothwell et al. (2011), Bell et al. (2007), and Reddy et al. (2008) and also with Hα and IR LFs at \(z \sim 2\) from Sobral et al. (2012) and Magnelli et al. (2011), respectively. We expect the IR LFs to probe the SFRs in the dominant population of dusty galaxies (ULIRG+LIRGs) at \(z \sim 2\). We use the relations from Kennicutt (1998) to convert the Hα and bolometric luminosities to SFRs. The SFR functions at \(z \sim 2\) are shown in the right panel of Figure 2; these SFR functions are in reasonable agreement with each other, except at the high-SFR end where the Hα LF is low. This may result from an incomplete sampling (or inadequate dust corrections) of dusty galaxies by the Hα study. The \(z \sim 2\) SFR functions are consistent with the evolution observed between \(z \sim 4–7\).

The bottom panel of Figure 3 (see also Table 3) shows SFR* for our results at \(z \sim 4–7\) with the SFR* from published studies mentioned above. The black symbols (Bouwens et al. 2007, 2011b; Reddy & Steidel 2009) represent the equivalent SFR* one would derive without applying a dust correction. There is a significant difference in the evolution of the high-SFR end of the SFR function taking dust attenuation into account: SFR* (without a dust correction) peaks at \(\sim 20 \text{M}_\odot \text{yr}^{-1}\) for \(z \sim 3–4\), while SFR* derived from dust-corrected UV or MIR LFs continues to increase from \(\sim 10 \text{M}_\odot \text{yr}^{-1}\) at \(z \sim 7\) to \(\sim 100 \text{M}_\odot \text{yr}^{-1}\) at \(z \sim 2\).

In Figure 4 we show the evolution of SFR* at fixed \(\phi_{\text{SFR}}^*\) (with \(\log_{10} \phi_{\text{SFR}}^* = -3.05\); see also Table 4). This is interesting since it allows us to examine the evolution in the high end of the SFR function without introducing additional “noise” from the SFR*–\(\phi_{\text{SFR}}^*\) degeneracy. We extend our comparison of SFR* to \(z \sim 8\) using the Oesch et al. (2012a) UV LF (see also Trenti et al. 2011; Bradley et al. 2012). The effect of the dust correction on SFR* decreases strongly with redshift for \(z \gtrsim 4\) and we expect the contribution at \(z \sim 8\) to be nearly negligible. We fit a linear slope to our own estimates of \(\log_{10} \phi_{\text{SFR}}^*\) at \(z \sim 4–7\) and find \(\log_{10} \phi_{\text{SFR}}^* = 2.43-0.22 (1+z)\) (Figure 4). The SFR functions without a dust correction follow \(\log_{10} \phi_{\text{SFR}}^* \propto -0.11 (1+z)\). Comparing the two, we see that our dust corrections double the rate at which the high-SFR end of the SFR function grows with...
cosmic time (see also the discussion in Section 6.2 in Bouwens et al. 2006).

Extrapolating the best-fit SFR*–redshift relation to higher and lower redshifts, we find good agreement with the $z \sim 2$ and $z \sim 8$ determinations of SFR* (Figure 4). The estimate for $z \sim 10$ from Oesch et al. (2012b) is also consistent with the trend, but the uncertainty in SFR* at that redshift is still quite large. The evolution of SFR* with redshift at fixed $\phi^*$ suggests that galaxies build up in a consistent way during the first 3 Gyr of cosmic time. Moreover, the excellent agreement between different probes of star formation across cosmic time provides a valuable cross-check on the validity of the dust corrections we use.

Papovich et al. (2011) also consider an evolving SFR versus redshift relation based on an abundance-matched selection. Not surprisingly, given that Papovich et al. (2011) use essentially the same UV LFs (from Bouwens et al. 2007, 2011b) and similar dust corrections at $z \gtrsim 4$ as we use here (from Bouwens et al. 2009 instead of Bouwens et al. 2012), they find similar SFRs over the range $z \sim 4$–8 (at constant number density $n(\text{SFR}) = 2 \times 10^{-4}$ Mpc$^{-3}$, see Table 4). However, the present analysis suggests much more clearly that the buildup in the SFRs of galaxies extends not simply from $z \sim 8$ to $z \sim 4$, but continues all the way to $z \sim 2$.

3.2. Low-SFR End: Flatter Slopes and Large Uncertainties

The low-end slope of the SFR function is interesting, since it provides us with insight into the physics and feedback effects in the lowest luminosity galaxies when compared to the dark matter halo mass function. The top panel of Figure 3 shows how the low-end slope $\alpha$ of the SFR function evolves as a function of redshift. The evolution of dust-corrected $\alpha_{\text{SFR}}$ contrasts with the original slope of the UV LF. $\alpha_{\text{SFR}}$ is typically $\Delta \alpha \approx +0.13$ flatter on average. Comparing $\alpha_{\text{SFR}}$ with similar determinations at lower redshift (Bothwell et al. 2011; Reddy et al. 2008; Sobral et al. 2012), we find no evidence for evolution with cosmic time.

4. SUMMARY

In this paper we combine UV LFs with dust corrections based on the UV-continuum slope $\beta$ and the IRX–$\beta$ relation, to produce SFR functions between $z \sim 4$–7. The dust correction results in a flatter faint-end slope and brighter $M_{\text{UV}}$.

We find SFR functions that, at fixed $\phi^*$, show a steady buildup in their value of SFR* with cosmic time, from $\sim 5 M_\odot$ yr$^{-1}$ at $z \sim 8$ to $\sim 100 M_\odot$ yr$^{-1}$ at $z \sim 2$, providing evidence that galaxies build up in a very uniform fashion in the first 3 Gyr (to $z \sim 2$). Use of the SFR function allows us to naturally link the evolution of normal star-forming galaxies at $z \gtrsim 4$ with the population of dusty star-forming galaxies seen at $z \sim 2$–3.

We thank Naveen Reddy, David Sobral, and Marcel van Daalen for useful discussions. We are thankful to Naveen Reddy for sending us the information necessary to make a comparison with the bright $z \sim 2$ spectroscopic sample from Reddy et al. (2010). Feedback from the referee significantly improved this paper. We acknowledge the support of an NWO vrije competitie grant, ERC grant HIGHZ 227749, and NASA grant HST-GO-11563.01. P.O. acknowledges support from NASA through a Hubble Fellowship grant 51278.01 awarded by STScI.

APPENDIX

MONTE CARLO SIMULATION TO RECOVER THE UV LF AND $\beta$–LUMINOSITY RELATION

In this study we derive SFR functions by transforming the UV LF using a luminosity-dependent dust correction. However, one might suppose that the dust correction may be better parameterized in terms of the SFR instead of the UV LFs. The Astrophysical Journal, 756:14 (8pp), 2012 September 1
dust attenuation, we obtain the observed UV luminosities based on the intrinsic $\beta$ measurements. The top right panel shows the simulated distribution as a function of UV luminosity, which we derive by dust correcting the bolometric luminosities based on the intrinsic $\beta$ values for the individual mock galaxies. The black squares indicate the mean $\beta$ we recover as a function of luminosity in these simulations, while the blue line gives the observed relation found in Bouwens et al. (2012). The bottom right panel shows that the UV LF we recover from these simulations (dot dashed lines) matches up well with the observed UV LF from Bouwens et al. (2007) at $z \sim 4$ (black circles and error bars).

(A color version of this figure is available in the online journal.)

Figure 5. Demonstration that we can use the SFR function to recover the two inputs to the SFR function as described in the Appendix. We show the bolometric luminosity function at $z \sim 4$ (equivalent to the SFR function with parameters in Table 2) in the lower left panel and a $\beta$ vs. bolometric luminosity relation (equivalent to a $\beta$ vs. SFR relation) in the upper left panel. The upper right panel shows the $\beta$ vs. observed UV luminosity relation we are attempting to reproduce with our simulations, and the lower right panel shows the UV LF. The gray area in the top left panel indicates our initial mock data set, with each mock galaxy having a $\beta$ drawn from a normal distribution with a mean $\langle \beta \rangle = -0.17(M_{\text{bol}} + 19.5) - 1.91$ and a $\sigma_{\text{int}}$ from the bolometric LF in the bottom left panel. Also plotted are the bolometric luminosities (red dots) and upper limits (orange arrows) of Reddy et al. (2010) based on their rest-frame UV luminosities and Spitzer MIPS 24 $\mu$m flux measurements. The top right panel shows the simulated distribution as a function of UV luminosity, which we derive by dust correcting the bolometric luminosities.

The steps in the simulation are as follows. We start with our derived SFR functions and then recover the two inputs to the SFR function, i.e., the rest-frame UV–Luminosity and the observed $\beta$–UV luminosity relation. This will allow us to test whether the SFR functions we derive are sensitive to our parameterizing the mean $\beta$ as a function of observed UV luminosity (instead of parameterizing it in terms of the SFR). We perform this test at $z \sim 4$, where both the observed UV–LF and the observed $\beta$–UV luminosity relation are best determined.

The results of our simulation are as follows. We start with our $z \sim 4$ SFR function and produce a mock data set with each galaxy in the data set having an SFR and $\beta$. The initial $\beta$-distribution is drawn from a normal distribution with a mean value equal to $\langle \beta \rangle = (d\beta/dM_{\text{bol}})(M_{\text{bol}} + 19.5) + \beta_{\text{int}}$ and a scatter equal to $\sigma_{\text{int}}$. This is shown with the gray area in the top left panel of Figure 5 as $\beta$ versus bolometric luminosity and the simulated bolometric LF is shown on the bottom left panel of Figure 5.

Assuming the Meurer et al. (1999) relation to calculate dust attenuation, we obtain the observed UV luminosities for each galaxy in this mock data set from the SFRs, as shown in the top right panel of Figure 5. We derive the $\beta$ versus SFR distribution in an iterative process so as to best reproduce the observed $\beta$–UV luminosity relationship with $\langle \beta \rangle = -0.11(M_{\text{UV,AB}} + 19.5) - 2.00$ and observed scatter $\sigma_{\text{obs}} = 0.34$ (Bouwens et al. 2012). The best-fit $\beta$ versus $M_{\text{bol}}$ distribution has the form $\langle \beta \rangle = -0.17(M_{\text{bol}} + 19.5) - 1.91$ and $\sigma_{\text{int}} = 0.30$.

As a check on our derived $\beta$ versus SFR distribution we have plotted the measurements from Reddy et al. (2010) in the top left panel of Figure 5. Reddy et al. (2010) use rest-frame UV and 24 $\mu$m observations of $z \sim 2$ galaxies to study the properties of star-forming galaxies as a function of their bolometric luminosities. The agreement between the bright-end of our simulated data set and the Reddy et al. (2010) measurements is encouraging, though we note that at fixed bolometric luminosity one might expect $z \sim 2$ galaxies to have somewhat higher dust content and therefore redder $\beta$ values than our $z \sim 4$ galaxies due to evolution in dust extinction versus SFR relation (e.g., Reddy et al. 2006; Buat et al. 2007). The Reddy et al. (2010) measurements therefore provide a rough upper limit to the steepness of the $\beta$–SFR relation at $z \sim 4$.

We convert the simulated observed distribution to an LF and compare this simulated observed UV LF with the UV LF of Bouwens et al. (2007; see the bottom right panel of Figure 5). The two LFs are in quite reasonable agreement. The characteristic luminosity $M^*$ we find is within 0.13 mag of the derived LF of Bouwens et al. (2007) and the faint-end slope $\alpha$ we find is within 0.03 of the slope Bouwens et al. (2007) find.
These differences are smaller than our current error bars for our SFR function parameters at \( z \sim 4 \).

This simulation gives us confidence that our derived SFRs are not subject to large biases due to incompleteness at the faint end of the distribution. Furthermore, these simulations suggest that dust extinction is not so large at the bright end of the LF that we are unable to approximately recover the SFR function. Overall, these test results provide some validation for our methodology for performing the dust corrections.

6 We also considered the possibility that our results are affected by scatter in the IRX–\( \beta \) relation at \( z > 4 \). For example, if we assume that dust extinction can be derived from the observed \( \beta \)-distribution and this \( \beta \)-distribution is a simple function of the SFR (as discussed in the Appendix), we estimate that a 0.2 dex scatter in the IRX–\( \beta \) relation could possibly result in a somewhat lower value of SFR* (\( \Delta \)SFR* \( \sim \) 0.09 dex). However, we could just as easily have assumed that dust extinction can be derived from the SFR of a galaxy and that scatter in the \( \beta \)-distribution at a given SFR is due to scatter in the IRX–\( \beta \) relation which would result in a somewhat higher value of SFR* (which is in the opposite sense from the previously discussed scenario). On balance, we cannot correct our results for the effects of scatter in the IRX–\( \beta \) relation unless we have detailed knowledge about how dust extinction, \( \beta \), UV luminosity, and SFR are correlated. In any case it would appear that any possible corrections are small, \( \sim \)0.1 dex, and one must be encouraged by how well our SFR function results match up with the LF results at \( z \sim 2 \).
