We systematically evaluate the potential energy at the touching configuration for heavy-ion reactions using various potential models. We point out that the energy at the touching point, especially that estimated with the Krappe-Nix-Sierk (KNS) potential, strongly correlates with the threshold incident energy for steep falloff of fusion cross sections observed recently for several systems at extremely low energies. This clearly indicates that the steep fall-off phenomenon can be attributed to the dynamics after the target and projectile touch with each other, e.g., the tunneling process and the nuclear saturation property in the overlap region.

DOI: 10.1103/PhysRevC.75.064612 PACS number(s): 25.60.Pj, 24.10.Eq, 25.70.Jj

Recently, for medium-heavy mass systems, it has become possible to measure fusion cross sections down to extremely low incident energies. In those measurements, unexpected steep falloff of fusion cross sections, as compared to a standard low incident energies. Although the steep fall-off phenomenon, referred to as the fusion hindrance, may be accounted for if one uses an anomalously large diffuseness parameter in the Woods-Saxon potential, the physical origin of the phenomenon has yet to be clarified.

One important aspect of fusion reactions at deep sub-barrier energies is that the inner turning point of the potential may be located far inside the touching point of the colliding nuclei. We show this schematically in Fig. 1. At energies close to the Coulomb barrier, the inner turning point is still far outside of the touching point [9] [see the line (i) in Fig. 1]. At these energies, one usually assumes that a compound nucleus is automatically formed once the projectile penetrates the Coulomb barrier, due to the strong nuclear attractive force in the classically allowed region. In contrast, at energies below the potential energy at the touching point, \( V_{\text{touch}} \), the inner turning point appears more inside of the touching point [see the line (ii) in Fig. 1]. That is, the projectile nucleus is still in the classically forbidden region when the two colliding nuclei touch each other. After the touching, an elongated composite system is formed, which evolves in the classically forbidden region between the projectile-like and the target-like fragments. Since this involves the penetration of the residual Coulomb barrier, naturally the fusion cross sections are hindered by the tunneling factor.

In this paper, we evaluate the potential energy at the touching configuration for several systems, and investigate whether the dynamics after the touching point is responsible for the steep fall-off phenomenon. In this respect, it is interesting to notice that the authors of Refs. [1,4] have argued that the steep fall-off phenomenon systematically takes place below a certain threshold incident energy, \( E_t \). We will show below that there is a strong correlation between the touching energy \( V_{\text{touch}} \) and the threshold energy \( E_t \), indicating that the density overlap in the classically forbidden region indeed plays an important role. We mention that one would have to settle a model in the overlap region, such as the adiabatic or sudden models, or some combination of these two, in order to clarify the whole dynamics of deep sub-barrier fusion reactions. However, our analysis is independent of these modelings, since both the adiabatic and the sudden approaches provide a similar potential energy to each other as long as the touching point is concerned.

In order to estimate the potential energy at the touching point, \( r_{\text{touch}} = R_P + R_T \), we employ the Krappe-Nix-Sierk (KNS) [10], the Bass [11], the proximity [12], and the Akyüz-Winter (AW) [13] models. Assuming the spherical shape for both the projectile and target nuclei, the KNS potential energy at the touching point reads

\[
V^{(N)}_{\text{KNS}} = -D \left( 4 + \frac{r_{\text{touch}}}{a} - \frac{f(R_P/a)}{g(R_P/a)} - \frac{f(R_T/a)}{g(R_T/a)} \right),
\]

where the functions \( f \) and \( g \) are defined as \( f(x) = x^2 \sinh(x) \) and \( g(x) = x \cosh(x) - \sinh(x) \), respectively. In this model, the nuclear radius is given by \( R = r_0 A^{1/3} \), and the depth constant \( D \) by

\[
D = \frac{4\sqrt{c_s (c_s + c_T)^3}}{r_0 r_{\text{touch}}} g(R_P/a) g(R_T/a) e^{-r_{\text{touch}}/a},
\]

where the effective surface energy constant \( c_s \) is given by \( c_s = a_s (1 - \kappa_s I^2) \) with \( I = (N - Z)/A \). We take the parameters to be \( a = 0.68 \text{ fm}, a_s = 21.33 \text{ MeV} \) and \( \kappa_s = 2.378 \) from FRLDM2002 [12], except for the radius parameter for which we slightly adjust to be \( r_0 = 1.2 \text{ fm} \) in order to fit the experimental fusion cross sections for the \(^{64}\text{Ni} + ^{64}\text{Ni} \) reaction at energies above the Coulomb barrier.

The proximity potential energy at the touching point is given by

\[
V^{(N)}_{\text{Prox}} = -1.7818 \frac{b R a_s}{r_0^2} - 3.00,
\]
where \( \overline{R} = R_T R_P / (R_T + R_P) \). In this model, the nuclear radius is given by
\[
R = R_{00} \left( 1 - \frac{7}{2} \frac{b^2}{R_{00}^2} - \frac{49}{8} \frac{b^4}{R_{00}^4} + \frac{N}{A} \right),
\]
with
\[
R_{00} = 1.240 A^{1/3} \left[ 1 + 1.646 / A - 0.191 (A - 2Z_A / A) \right],
\]
\[
t = \frac{3}{2} \frac{J(N-Z)/A - \frac{1}{12} c_1 Z A^{-1/3}}{Q + \frac{2}{3} J A^{-1/3}}.
\]
The value of the parameters are taken to be \( b = 1 \) fm, \( r_0 = 1.14 \) fm, \( J = 32.65 \) MeV, \( c_1 = 0.757895 \) MeV, and \( Q = 35.4 \) MeV.

The Bass potential energy at the touching point is given by
\[
V^{(N)}_{\text{Bass}} = -\overline{R} [\alpha + \beta]^{-1},
\]
where the parameters \( \alpha \) and \( \beta \) are taken as \( \alpha = 0.0300 \) MeV\(^{-1}\) fm and \( \beta = 0.0061 \) MeV\(^{-1}\) fm, respectively. In the Bass model, the nuclear radius is given by \( R = 1.16 A^{1/3} - 1.39 A^{-1/3} \). The AW potential energy at the touching point, on the other hand, reads
\[
V^{(N)}_{\text{AW}} = -8 \pi \gamma \overline{R} a,
\]
where the average surface tension \( \gamma \) is given by \( \gamma = 0.95 [1 - 1.8 (N/Z_A)^{1/3} / A] \) MeV fm\(^{-2}\). In this model, the nuclear radius is given by \( R = (1.20 A^{1/3} - 0.09) \) fm and the diffuseness parameter \( a \) is given by \( a = 0.855 \times [1 + 0.53 (A^{1/3} + A^{-1/3})]^{-1} \) fm.

In order to estimate the total potential energy at the touching point, \( V_{\text{touch}} \), one has to add the Coulomb potential to the nuclear potential energies given by Eqs. (3)–(8). To this end, we use the Coulomb potential for two point charges, \( V^{(C)} = e^2 Z_T Z_P / r_{\text{touch}} \), where the touching radius \( r_{\text{touch}} \) is specified for each model for the nuclear potential, \( V^{(N)} \). The resultant touching energy for the systems discussed in Ref. [5] is shown in Fig. 1 as a function of \( Z_T Z_P \mu^{1/2} / c \), where \( \mu \) is the reduced mass of the colliding nuclei. The results of the KNS, the Bass, the proximity and the AW models are denoted by the open circle, the open triangle, the open diamond, and the open square, respectively. All the results are summarized in Table I. These touching energies are compared with the energy \( E_T \), at which the experimental fusion cross section is maximum when it is plotted in terms of the astrophysical S-factor [5]. These “experimental” energies \( E_T \) are shown in Fig. 2 by the filled circles, the filled squares, the filled triangles, and the horizontal lines, depending on the types of the system as defined in Ref. [5]. Notice that the energy \( E_T \) for the type III was estimated by extrapolation, and that for the type IV is only an upper limit. The systematics for the energy \( E_T \) proposed by Jiang et al. [5] is also shown by the solid line.

Although the physical significance for the energy \( E_T \) is not clear, because the S-factor representation for fusion cross sections would be useful only at much lower energies than the lowest energies of the current measurements, at which the outer turning point is much larger than the inner turning point (see, e.g., Refs. [17,18] for a discussion on the modified S-factor, that takes into account the effect of the inner turning point), it is remarkable that the result of the KNS model follows closely to the energy \( E_T \), and thus the systematics shown by the solid line (an exceptional case of \(^{64}\text{Ni} + ^{100}\text{Mo} \) will be discussed in the next paragraph). The good correspondence between \( V_{\text{KNS}} \) and \( E_T \) may be due to the fact that the KNS model partly takes into
TABLE I. Potential energy at the touching configuration calculated by various theoretical models for the systems discussed in Ref. [5]. In the second column, $Z_T Z_P$ is the charge product of the system, while $\mu$ is the reduced mass. $X_{\text{eff}}$ is the effective fissility parameter defined as $X_{\text{eff}} = Z_T Z_P / [A_T^{1/3} A_P^{1/3} (A_T^{1/3} + A_P^{1/3})]/12.6$, while $E_s$ is the experimental energy at which the astrophysical S-factor has the maximum [5]. $V_{\text{KNS}}$, $V_{\text{POX}}$, $V_{\text{Bass}}$, and $V_{\text{AW}}$ denote the results of the Krappe-Nix-Sierk, the proximity, the Bass, and the Akyüz-Winther models, respectively.

account the saturation of nuclear matter when two nuclei come inside the Coulomb barrier [19] (in fact, the KNS model has been shown to be consistent with the energy density formalism with the Skyrme SkM* interaction [20,21]). The result of the AW potential is similar to that of the KNS model, although the deviation from $E_s$ is slightly larger. For the Bass and the proximity models, although the dependence of the touching energy $V_{\text{touch}}$ on the parameter $Z_T Z_P \mu^{1/2}$ is similar to that of the KNS and the AW models, there is a large discrepancy between the touching energy $V_{\text{touch}}$ and the threshold energy $E_s$.

For the asymmetric $^{64}\text{Ni} + ^{100}\text{Mo}$ reaction, the experimental threshold energy $E_s$ deviates largely from the systematics curve. The calculations with the KNS and AW models are consistent with the systematics curve but not to the value of $E_s$. In order to check how the touching energy $V_{\text{touch}}$ compares with the threshold energy $E_s$ for other asymmetric systems, we also examine the $^{16}\text{O} + ^{208}\text{Pb}$ reaction. For this system, we find that the KNS model leads to the touching energy $V_{\text{touch}}$ that is consistent with the experimental threshold energy $E_s$ [3] (see Table II). Therefore, it is unlikely that the large difference between $V_{\text{touch}}$ and $E_s$ for the $^{64}\text{Ni} + ^{100}\text{Mo}$ system can be attributed to the model assumption of the KNS potential. Notice that for this system, there may exist some peculiar nuclear structure effect, because the coupled-channels calculation reported in Ref. [22] does not seem to account well for the experimental fusion cross sections even above the threshold energy $E_s$. A further investigation is necessary for this system concerning the threshold energy.

In order to see more clearly the correlation between $E_s$ and $V_{\text{KNS}}$, the lower panel of Fig. 3 shows these energies as

TABLE II. The potential energy at the touching configuration calculated with the KNS model for the systems discussed in Refs. [2–4]. All of these systems are categorized as type III.

| System | $Z_T Z_P \sqrt{\mu}$ (MeV$^{1/2}$/c) | $X_{\text{eff}}$ (MeV) | $E_s$ (MeV) | $V_{\text{KNS}}$ (MeV) | Ref. |

except for large $X_{\text{eff}}$, clearly indicating that there is a strong correlation between these two values. The large discrepancy for systems with large $X_{\text{eff}}$ may be due to the ambiguity of the experimental data, because the measurements were only for the fusion-evaporation cross sections and the fusion-fission cross sections were estimated using the statistical model [2–4].

In summary, we have shown that the potential energy at the touching point strongly correlates with the threshold incident energies for the steep falloff of the fusion cross sections. The systematics of the threshold energy can be rather naturally explained by the present approach in terms of the touching energy. This strongly suggests that the overlap process after the touching is responsible for the steep falloff of the fusion cross section. For such overlap process, the sudden and adiabatic approaches have been often employed [23,24]. In the former, the frozen density approximation while overlapping with the colliding nuclei is applied, and in the latter, the dynamical change in the density of the colliding nuclei is taken into account. These two approaches are in the opposite limit to each other, and there is not yet a definite consensus regarding which limit better describes the realistic situation at deep sub-barrier energies. In this respect, the threshold energy discussed in this paper will provide a useful constraint to modeling of the overlap process as the touching configuration is a doorway of such process.
