We characterize the nonlinear stage of modulational instability (MI) by studying the long-time asymptotics of focusing nonlinear Schrödinger (NLS) equation on the infinite line with initial conditions that tend to constant values at infinity. Asymptotically in time, the spatial domain divides into three regions: a far left field and a far right field, in which the solution is approximately equal to its initial value, and a central region in which the solution has oscillatory behavior and is described by slow modulations of the periodic traveling wave solutions of the focusing NLS equation. These results demonstrate that the asymptotic stage of MI is universal, since the long-time behavior of a large class of perturbations is described by the same asymptotic state.

Introduction. Modulational instability (MI) — i.e., the instability of a constant background to long wavelength perturbations — is one of the most ubiquitous phenomena in nonlinear science (e.g., see [1] and references therein). The effect, which is known as Benjamin-Feir instability in the context of deep water waves [2], has been known since the 1960’s, but has received renewed attention in recent years, and was also linked to the formation of rogue waves in optical media [3, 4] and in the open sea [5].

In many cases, the dynamics of systems affected by MI is governed by the one-dimensional focusing nonlinear Schrödinger (NLS) equation, which models the evolution of weakly nonlinear dispersive wave packets in such diverse fields as water waves, plasmas, optics and Bose-Einstein condensates. One can therefore study the initial (i.e., linear) stage of MI by linearizing the NLS equation around the constant background. One easily sees that all Fourier modes below a certain threshold are unstable, and the corresponding perturbations grow exponentially. However, the linearization ceases to be valid as soon as perturbations have become comparable with the background. A natural question is then what happens at this point, which is referred to as the nonlinear stage of MI. Surprisingly, a precise characterization of the nonlinear stage of MI for generic, finite-energy perturbations has remained by and large an open problem for the last fifty years.

The NLS equation is a completely integrable system [6], and admits an infinite number of conservation laws and exact $N$-soliton solutions for arbitrary $N$, describing the elastic interaction of solitons [6]. By analogy with the case of localized initial conditions, a natural conjecture was that MI is therefore mediated by solitons [7, 8]. The initial value problem (IVP) for the NLS equation can be solved via the inverse scattering transform (IST). In particular, the IST for the focusing NLS equation with zero boundary conditions (ZBC) at infinity (i.e., localized disturbances) was done in [6], and the IST for the defocusing NLS equation with nonzero boundary conditions (NZBC, i.e., solutions that tend to finite value at infinity) was done in [9]. But only partial results [10–12] were available for the focusing NLS equation with NZBC until recently, in [13], we developed a complete IST for this case. (Recall that the IST for systems with NZBC is notoriously more challenging, and the IVP for the vector NLS with NZBC was also only solved recently [14, 15].) In [16] we then used the IST to study MI by computing the spectrum of the scattering problem for simple classes of perturbations of a constant background. In particular, we showed that there are classes of perturbations for which no solitons are present. Thus, since all generic perturbations of the constant background are linearly unstable, solitons cannot be the mechanism that mediates the MI, which contradicts a recent conjecture [7]. Instead, in [16] we identified the instability mechanism within the context of the IST, by showing that the instability comes from the continuous spectrum of the scattering problem associated with the NLS equation (see below for further details).

In this Letter we use the framework developed in [13] to characterize the nonlinear stage of MI. We do so by studying the long-time asymptotic behavior of localized perturbation of the constant background. We show that, generically, the long-time asymptotics of modulationally unstable fields on the whole line displays universal behavior, and decomposes the $xt$-plane into two plane wave regions — in each of which the solution is approximately equal to the background up to a phase — separated by a central region in which the leading order behavior is described by a slowly modulated traveling wave solution.

The NLS equation and MI. We write the focusing NLS equation as

$$iq_t + q_{xx} + 2(|q|^2 - q_0^2)q = 0,$$

where $q(x, t)$ represents the complex envelope of a quasi-monochromatic, weakly nonlinear dispersive wave packet, and the physical meaning of the variables $x$ and $t$ depends on the physical context. (E.g., in optics, $t$ represents propagation distance while $x$ is a retarded time.) Here $q_0 = |q_\pm| > 0$ is the background amplitude, and the NZBC satisfied by the field are

$$q_\pm = \lim_{x \to \pm \infty} q(x, t)$$

The term $-2q_0^2 q$ has been added to Eq. (1) so that $q_\pm$ are independent of time, and can be removed by a trivial gauge transformation.
The constant background solution is simply $q_0(x,t) = q_0$. Linearizing Eq. (1) around this solution, one finds that all Fourier modes with $|\zeta| < 2q_0$ (where $\zeta$ is the Fourier variable) are unstable, and that the growth rate is $\gamma(\zeta) = |\zeta| \sqrt{4q_0^2 - \zeta^2}$. Below we will use the IST for Eq. (1) with the NZBC (2), that was developed in [13], slightly reformulated in a way that is more convenient for the present purposes.

Recall that the NLS Eq. (1) is the zero-curvature condition $X_t - T_x + [X,T] = 0$ of the matrix Lax pair $\phi_t = X\phi$ and $\phi_x = T\phi$, with $X = i\alpha_3 + Q$ and $T = -i(2k^2 + q_0^2 - |q|^2 - Q_3)\sigma_3 - 2kQ$, where $Q_3 = \text{diag}(1, -1)$ is the third Pauli matrix, and

$$Q(x,t) = \begin{pmatrix} 0 & q \\ -q^* & 0 \end{pmatrix}.$$  

As usual, the first half of the Lax pair is referred to as the scattering problem and $q(x,t)$ as the potential, and the direct problem in the IST consists in determining the scattering data (i.e., reflection coefficient, discrete eigenvalues and norming constants) from the IC. This is done through the Jost eigenfunctions $\phi_{\pm}(x,t,k)$, which are the simultaneous matrix solutions of both parts of the Lax pair which reduce to plane waves, namely, $\phi_{\pm}(x,t,k) = E_{\pm}(k) e^{i\theta(x,k)} + o(1)$ as $x \to \pm\infty$, where $\pm i\lambda$ and $E_{\pm}(k) = 1 + i(k + \lambda)\sigma_3Q_{\pm}$ are respectively the eigenvalues and corresponding eigenvector matrices of $X_{\pm} = \lim_{x \to \pm\infty} X$, with $\lambda(k) = (k^2 + q_0^2)^{1/2}$ and $\theta(x,t,k) = \lambda x - \omega t$, and where $\omega(k) = 2k\lambda$. These Jost eigenfunctions, which are the nonlinearization of the Fourier modes, are defined for $k \in \mathbb{C}$ such that $\lambda(k) \in \mathbb{R}$, which defines the continuous spectrum $\Sigma = \mathbb{R} \cup i[-q_0, q_0]$, see Fig. 1(left). The scattering relation $\phi_-(x,t,k) = \phi_+(x,t,k)A(k)$ defines the scattering matrix $A(k)$ for $k \in \Sigma$, and the corresponding reflection coefficient is $r(k) = -a_{21}/a_{22}$. The zeros of $a_{11}(k)$ and $a_{22}(k)$ define the discrete spectrum of the problem, which leads to solitons. As usual, time evolution within IST is trivial. In particular, with the above normalization of the Jost eigenfunctions, all the scattering data are independent of time.

The focusing NLS Eq. (1) with the NZBC (2) possesses a rich family of soliton solutions [10, 17–19], classified according to the possible placements of the discrete eigenvalue [13]. In particular, the so-called Akhmediev breathers provide a good representation for the growth of seeded perturbations [20, 21]. Importantly, however, Akhmediev breathers are periodic in space, and therefore possess infinite energy. Hence they cannot describe the asymptotic state of localized (i.e., finite-energy) perturbations of the constant background. Moreover, as mentioned earlier, generic perturbations of the constant background exist for which no discrete spectrum (and thus no solitons) is present. Instead, the key to describe the asymptotic stage of MI lies in the continuous spectrum. Indeed, as we showed in [16], $\omega(k)$ is purely imaginary for $k \in i[-q_0, q_0]$, and the Jost solutions for $k \in i[-q_0, q_0]$ are precisely the nonlinearization of the unstable Fourier modes. In fact, even their growth rate is the same, modulo the usual rescaling.

The inverse problem in the IST consists in reconstructing the solution $q(x,t)$ of the NLS equation from the scattering data, and is formulated in terms of a Riemann-Hilbert problem, namely the problem of reconstructing the meromorphic matrix $M(x,t,k)$ defined as $M(x,t,k) = (\phi_+1/\phi_+, k_2) e^{-i\theta_3}$ for $k \in \mathbb{C} \setminus \{0, q_0\}$ and $M(x,t,k) = (\phi_{-1}, \phi_+/a_{11}) e^{-i\theta_3}$ for $k \in \mathbb{C} \setminus i[-q_0, 0]$, where $\Sigma = \{k \in \mathbb{C} : \text{Im } k \geq 0\}$ and $\phi_{\pm,j}$ for $j = 1,2$ denote the columns of $\phi$. This is done by using the scattering relation and symmetries to obtain a jump condition $M^+(x,t,k) = M^-(x,t,k)V(x,t,k)$ for $k \in \Sigma$, where superscripts $\pm$ denote projection from the left/right of the contour $\Sigma$ (oriented rightward along the real $k$-axis and upward along the segment $i[-q_0, q_0]$). Explicitly,

$$V(x,t,k) = \left\{ \begin{array}{ll} 1 + |r|^2 & r e^{2i\theta} \\
q_0 & re^{-2i\theta} \\
r e^{-2i\theta} & 1 \\
\frac{i q_0}{k - \lambda} & 1 + |r|^2 - re^{-2i\theta} \end{array} \right\}_{k \in i[0, q_0]} ,$$

plus a symmetric expression for $k \in i[-q_0, 0]$. Note that $\det M(x,t,k) = 1$ for $k \in \mathbb{C} \setminus \Sigma$ and $M(x,t,k) \to 1$ as $k \to \infty$. The solution of the NLS is recovered via the usual reconstruction formula $q(x,t) = -2i \text{lim}_{k \to \infty} kM_{12}$. The signature of MI in the inverse problem is the exponentially growing entries of $V(x,t,k)$ for $k \in i[-q_0, q_0]$ through the time dependence of $\theta(x,t,k)$.

**Long-time asymptotics of finite-energy perturbations.** We now study the asymptotic state of MI for generic, finite-energy perturbations of a constant background. As mentioned earlier, we do so by computing the long-time asymptotics of the solutions of the focusing NLS equation with NZBC. As a concrete example we consider box-like perturbations with $q(x,0) = q_0$ for $|x| > L$ and $q(x,0) = b e^{i\beta}$ for $|x| < L$, in which case $r(k) = q^{2i\mu}(b \cos \beta - q_0)k - i\lambda b \sin \beta / [\lambda \mu \cot(2L\mu) - i(k^2 + q_0b \cos \beta)]$, with $\mu = \sqrt{k^2 + b^2}$. The calculations, however, apply to all localized perturbations such that the cor-

Asymptotic stage of MI. As the implementation of the DZ method is complicated, the details will be reported elsewhere. On the other hand, the main results can summarized in a straightforward way. The key piece of information in the deformation of the RHP is the sign structure of \( \Im \theta \) in the complex \( k \)-plane for various values of \( \xi \) for \( q_0 = 1 \): (i) \( \xi = -6 \), corresponding to \( x < -\xi_s t \); (ii) \( \xi = -5.2 \), corresponding to \( -\xi_s t < x < 0 \); (iii) \( \xi = 3 \), corresponding to \( 0 < x < \xi_s t \); (iv) \( \xi = 6.5 \), corresponding to \( x > \xi_s t \). Gray: \( \Im \theta > 0 \). White: \( \Im \theta < 0 \).

FIG. 2: The sign structure of \( \Im \theta \) in the complex \( k \)-plane for various values of \( \xi \) for \( q_0 = 1 \): (i) \( \xi = -6 \), corresponding to \( x < -\xi_s t \); (ii) \( \xi = -5.2 \), corresponding to \( -\xi_s t < x < 0 \); (iii) \( \xi = 3 \), corresponding to \( 0 < x < \xi_s t \); (iv) \( \xi = 6.5 \), corresponding to \( x > \xi_s t \).
reflection coefficient, whereas the structure of the solution as a modulated elliptic wave is independent of it. In this sense, the asymptotic stage of MI is universal.

Since the NLS equation has a wide range of applicability, from nonlinear optics to deep water waves, acoustics, plasmas and Bose-Einstein condensates, we expect that the results of this work will apply to all of the above physical contexts. The results also have potential connections to the phenomena of rogue waves [3, 4] and integrable turbulence [35].

The results of this work should be compared to those in the case of periodic boundary conditions (BC). There, the instability is ascribed to the presence of homoclinic solutions [30]. The initial stage of MI was studied in [31] with a 3-mode model. But the machinery used to solve the IVP in the periodic case (namely, the theory of finite-genus solutions [32, 33]) is very different from that used here. The limiting process from the periodic case to the infinite line is highly nontrivial, and has not been properly understood yet. Most importantly, the physics in the two cases is different. For example: (i) In the periodic case there is an amplitude threshold below which no instability occurs, whereas no such threshold exists on the infinite line. (ii) In the periodic case, radiation cannot escape to infinity, and therefore it is doubtful that a long-time asymptotic state even exists.

The above results can also be compared to the semiclassical limit of the focusing NLS equation with ZBC [34]. The study of that scenario requires more sophisticated analysis, and the results are also more complicated [39]. Moreover, numerical simulations of the semiclassical case become more and more sensitive to round-off error as \( h \to 0 \) [30]. (Essentially, the IVP becomes ill-posed in that limit.) In contrast, the present case does not appear to be as sensitive. As a result, there are no fundamental obstacles to the possibility that the behavior described in this work could observed experimentally. The robustness of the analytical predictions is confirmed in Fig. 3, which shows a numerical simulations of Eq. (1) with a small Gaussian perturbation of the constant background.

Semiclassical limits and long-time asymptotics problems are often studied using Whitham theory [22]. But the Whitham equations for the focusing NLS equation are elliptic, and therefore the corresponding IVP is ill-posed. This is well known in the case of ZBC (e.g., see [34]), and it remains true in the case of NZBC. While special solutions to the Whitham equations also exist in the focusing case [28, 29], it should be clear that the IST-related methods used here are the only way to study the nonlinear stage of MI for generic perturbations of the constant background. Indeed, we see no obstacles to generalizing the present calculations to include the presence of discrete eigenvalues, which will allow for the first time a study of the interactions between solitons and radiation in modulationally unstable media.

36. The point $x = 0$ appears to be special because, in the far field approximation of the dynamics arising from localized perturbations, everything seems to arise from the origin, just like in the far-field asymptotics for linear problems [22].
37. This solution was first studied in [28, 29] in the context of Whitham theory, but neither work studied the evolution of generic initial conditions.
38. Here $K(m)$ is the complete elliptic integral of the first kind. Since the wave is nonlinear, the wavenumber and period are not related by a simple proportionality relation as for harmonic waves.
39. Although there is a similar bifurcation from plane waves to modulated genus-2 oscillations in the case of ZBC, the genus-2 solution also breaks along a certain caustic curve in the $xt$-plane, with numerical evidence indicating the presence of regions of higher and higher genus in the limit $\hbar \to 0$.
