Semantic Place Understanding for Human-Robot Coexistence - Towards Intelligent Workplaces

Stefano Rosa, Andrea Patanè, Chris Xiaoxuan Lu, Niki Trigoni

Abstract—Recent introductions of robots to everyday scenarios have revealed unprecedented opportunities for collaboration and social interaction between robots and people. However, to date, such interactions are hampered by a significant challenge: having a semantic understanding of their environment. Even simple requirements, such as “a robot should always be in the kitchen when a person is there”, are difficult to implement without prior training. In this paper, we advocate that robot-people co-existence can be leveraged to enhance the semantic understanding of the shared environment, and improve situation awareness. We propose a probabilistic framework that combines human activity sensor data generated by smart wearables with low level localisation data generated by robots. Based on this low level information and leveraging colocation events between a user and a robot, it can reason about the two types of semantic information: 1) semantic maps, i.e. the utility of each room, and 2) space usage semantics: tracking humans and robots thru rooms of different utilities. The proposed system relies on two-way sharing of information between the robot and the user. In the first phase, user activities indicative of room utility are inferred from wearable devices and shared with the robot, enabling it to gradually build a semantic map of the environment. In the second phase, via colocation events, the robot teaches the user device to recognize the type of room where they are co-located. Over time, robot and user become increasingly independent and capable of semantic scene understanding.

I. INTRODUCTION

High-level semantic understanding of the environment is still an open problem for complex cyber physical systems involving robots and people. We envision that in the next five years, such systems will become ubiquitous: robots’ presence will continue to grow in workplaces, and low cost robots will increasingly assist humans in domestic environments. The use of wearable sensors in manufacturing has been investigated, with a particular focus on augmented reality and dedicated assistance [2], [18]. Existing robotic and wearable sensor systems, however, still lack maturity in terms of how they perceive the environment.

For example, robots typically perceive space in terms of low-level metric, topological or feature maps. Recent work has motivated the need for a high level understanding of the environment (e.g., semantic, affordances or high-level geometry) in order to enable emerging robotics applications [8]. To date, vision-based techniques for semantic mapping are well studied, but they are labour intensive as they require careful training and/or fine-tuning. Our vision instead is that semantic information can be automatically acquired by robots over time as a result of coexistence with users.

Similarly, wearable devices held by humans, e.g. smartphones or smartwatches, require tedious training (e.g. WiFi fingerprinting) and/or bespoke sensor infrastructure (e.g. UWB/Bluetooth) to localise themselves within a room, and even then, they lack semantic understanding of the utility of the room. Again, we advocate that this capability should be acquired spontaneously by human-held devices as a result of them interacting with robots.

To this end, we propose a system that enables robots and wearable devices to have a semantic understanding of their environment via colocation and interaction with each other. We believe that this is key to a variety of applications, from issuing simple commands to robots such as “Go to the kitchen”, to tasks of collaborative nature like “The robot should go to the kitchen when the user (her smartphone) is there”. In an industrial scenario, room-level localisation of users could enable real-time dynamic context-aware reasoning [4], in particular in the framework of Industry 4.0, in which the use of arrays of sensors on the shop-floor could be replaced by a few mobile sensors, carried by autonomous mobile service robots and by users.

The first intuition behind our approach is that user activities provide informative hints about the utility of each room. For example, a bedroom can be easily identified if people often sleep in that room. However, the association between room types and activities is not always unique. For instance, a user may eat in the dining room most of the time, but may occasionally opt to do so in the living room. The problem that arises is how to reliably infer semantic labels for different rooms of the space given two incomplete and noisy sources, i.e., robots’ perception of space and users’ activity context.

Once we address the problem of semantic mapping, it paves the way for inferring the sequence of room types that human devices traverse. A robot, who is now aware of semantic room labels, can teach human mobile devices how to recognize them based on their own signals. Specifically, we show how a robot can help mobile devices to tune the parameters of the Hidden Markov Model (HMM) that they use for localisation.

To summarise, semantic mapping and semantic localisation are two faces of the same coin; we address both by leveraging opportunistic colocation events between robots and human-held devices. Thru the diverse lenses of robots and wearable devices, we show that they can both develop a semantic understanding of their space.

In particular, the contributions of this work are as follows:

• A method for inferring semantic labels (room types)
for different rooms by exploiting user activities and opportunistic colocation events.

- A method for exploiting the inferred semantic map and colocations in order to train the parameters of a Hidden Markov Model (HMM) for user localisation.
- We propose a bidirectional recurrent neural network with approximate variational inference for classification of complex daily activities from a smartwatch.
- We validate the results in two work environments co-inhabited by robots and humans wearing smartwatches.

The remainder of the paper is structured as follows: Section II provides an overview of related work; Section III presents the architecture of our system; Section IV describes the training of the HMM for user localisation; Section V discusses the training of the HMM for user localisation; Section VI evaluates the proposed approaches in different scenarios and Section VII presents our conclusions and directions for future work.

II. RELATED WORK

Daily activity recognition Activity recognition, and in particular wearable activity recognition, is an important problem that has drawn significant attention from the research community in the last 10 years. Although different sensor modalities have been studied, we focus on the most related work that uses inertial sensor data (acceleration and gyroscope) for activity recognition. We first discuss recent work on classifying activities, and then discuss how activity information has been used within simultaneous localisation and mapping (SLAM) frameworks.

In [22] the authors use inertial data from a wrist-mounted device to detect activities performed on household objects. In [21] the authors propose to combine smartwatches and smartphones for activity recognition and evaluate different features. A Deep Belief Network (DBN) composed by stacked Restricted Boltzmann Machines (RBMs) is used in [5] for detecting activities based on spectrograms of acceleration data. A hybrid of deep learning and hidden Markov models (DL-HMM) is also presented for sequential activity recognition. An alternative dense approach of labelling each sensor sample in a sequence, as opposed to labelling a whole window of data, is explored using fully convolutional networks in [31]. The above papers focus entirely on improving activity recognition; in this paper, we propose a novel approach to activity recognition, based on variational LSTMs, that gives us estimates of classification uncertainty. This is a distinct advantage as it enables us to integrate the activity classification model into a purely probabilistic model, wherein uncertainty about activity translates to uncertainty about semantic room labels in a principled manner.

We are now in a position to overview how activity classification has been explored within simultaneous localisation and mapping frameworks. In [13] the authors proposed a 3D SLAM algorithm for users wearing wearable sensors, by including detected activities as landmarks in a particle filter SLAM approach. In [12] the approach is extended into a unified Bayesian framework for semantic SLAM with the goal of adding robustness to errors in activity recognition. However, in both approaches the user carries a multitude of inertial sensors (wrist-mounted, hip-mounted, foot-mounted IMUs), and does not exploit interactions with robots. Moreover, while the approach is shown to work on some medium-length trajectories, particle filter based SLAM methods are known to suffer from the forgetting problem over longer trajectories (due to the nature of re-sampling, the best trajectory could be discarded over time). In [16] a method is proposed for tagging maps with objects. The object’s position is inferred by detecting user activities and location, but the detected activities are not used in the map estimation and there is no information exchange between the robot and the user. To our knowledge this is the first paper that infers both user activity and its uncertainty from noisy wearable sensors, and feeds this information to co-located robots, which then learn semantic maps of the environment.

Semantic mapping Semantic mapping is the problem of associating high-level semantic attributes to low-level geometric features. Both perception and suitable map representations are active areas of research, but to date most work in the robotics community has been devoted to camera sensors [7]. [20] presents a conceptual model for semantic map representation, with different levels of abstraction, from sensor data to concepts, such as rooms, with associated properties, such as shape, appearance, and detected objects. The layered structure of the spatial knowledge is used for reasoning at the semantic level, starting from laser range finders and camera sensors. A number of works have focused on assigning semantic concepts to high level map features such as planar surfaces [23], [19] segments known objects in the map based on semantic labels. Recently, [29] proposed a novel recurrent neural network architecture for semantic mapping on RGB-D videos. Semantic information is integrated with dense 3D SLAM techniques such as KinectFusion in order to obtain a 3D semantic map of the environment. The most closely related work on semantic mapping is recent work on inferring room labels [24] using visual place categorization. A convolutional neural network is trained on the SUN Scene Understanding dataset, and addresses the closed-set limitation by training a set of one-vs-all classifiers for recognizing new semantic classes.

The above techniques rely on training data that associate visual sensor data to higher level semantic labels. Such learning tends to be very sensitive to the environment and incurs a significant manual fine tuning effort in each environment. For example, the appearance of a kitchen may vary significantly across different work and home environments. In our work, we avoid environment specific training; we rely on activity inference that transfers well between different environments, and exploit robot-person interaction to gradually learn room types from user activities over time. The only other work that exploited robot-person interaction is [16], but only to perform activity and associated object recognition in a more reliable manner by combining the camera sensor of the robot with the inertial sensors of the user.

User localisation Indoor localisation techniques have gained significant maturity offering both infrastructure-based (e.g. UWB [3], acoustic [25], Bluetooth Low Energy (BLE)
beacons [34] and infrastructure-less (e.g. WiFi [17], [26], geomagnetic [27] and inertial [30]) solutions. In general, infrastructure-based methods require the deployment and maintenance of bespoke localisation hardware, which greatly limits their application. On the other hand, infrastructure-less methods exploit ambient signals in the environment and are less costly. However, these methods typically require offline training in the form of learning signal maps of WiFi or geomagnetic signals. The user’s positions can be then localized by matching the online collected signals with the surveyed signal map. Even after significant training effort, location estimation can still be inaccurate in the online phase due to the environmental dynamics and pose variations of users.

Unlike previous work on learning physical signal maps, the adopted semantics are abstract and tightly related to user activities. In our context, the aim is to infer semantic paths, e.g., the user went from the conference room to the kitchen and back to his office. Previous work [15] on combining user activities with WiFi and acoustic data to localise users at room-level in domestic environments required a labour-intensive training phase for building the WiFi map. Instead, we move away from location-based training efforts, and rely on lifelong learning from human-robot interactions. The idea is to progressively build confidence on the semantics of different rooms, and make wearable devices increasingly aware of their environment.

III. SYSTEM ARCHITECTURE

This section provides a high level overview of our system. We start by describing its actors and their sensing capabilities, and then proceed to overview the two main components of the system.

A. Actors and sensing capabilities

The proposed system includes two types of actors: a mobile assistive robot and a user holding a wearable device, e.g. a smartwatch. No other infrastructure is necessary.

Mobile robot We assume that the mobile robot is equipped with proprioceptive sensors, such as wheel encoders or an inertial sensor and an exteroceptive distance sensor such as a laser range finder, sonars, or infrared sensors. Those sensors are required in order for the robot to create a map of a previously unseen environment and localise therein, as well as perform basic navigation in it. We don’t rely on camera sensors, since cameras are often forbidden in workplaces for privacy reasons, and would also pose privacy issues in home environments.

User We make the assumption that the user is carrying a smart device, e.g. a smartwatch on his right arm if right-handed or left arm if left-handed. Smartwatches are a sensible choice for detecting human activities from inertial data, and are not intrusive compared to other sensors. Smartphones can be used to infer low-level activities such as walking, resting, climbing stairs, etc., but are not useful for detecting a richer set of daily activities, such as washing hands. It should be noted, however, that smartwatches still present some limitations when having to distinguish between activities that present similar motions, e.g., washing hands and washing dishes. In this paper we model such uncertainty and take it into account in building semantic maps and localising users within them.

B. System components

Our system consists of two main sub-systems, one responsible for building the semantic map of the environment, and one for localising users with wearables within the semantic map. These two sub-systems are discussed below in more detail.

Semantic Mapping Figure 1 provides an overview of the first sub-system, designed to infer the semantic labels of map cells. In this phase, we assume that the robot has already built a grid map representation of the environment using an existing Simultaneous Localisation and Mapping (SLAM) algorithm, such as gmapping. The robot is also able to localise in the map using its sensors and a suitable localisation algorithm such as amcl. Moreover, the robot is able to navigate the environment by planning trajectories and avoiding obstacles. Such aspects of robot functionality are already mature and accessible to researchers and practitioners in mobile robotics.

The user is wearing a smartwatch, which is acquiring inertial measurements (accelerations and angular velocities). Based on these measurements, we infer probability distributions of activities using bidirectional long-short term memory neural networks. Whenever the robot happens to be colocated with the user in the same room, the robot detects the human figure with its sensors and registers the colocation event.

The semantic map subsystem takes as input motion data from the user, metric / topological maps inferred from the robot, and colocation events detected by the robot, and combines them to infer semantic labels for each grid cell of the robot map. Details are further discussed in Section IV.

Semantic Localisation Having obtained a semantic map of the environment thru the previous process, our system includes a second component for localising users within the semantic map, as shown in Figure 2. Our aim is to infer trajectories that are not sequences of time-x-y-floor coordinates, but sequences of time-roomLabel tuples.

In order to obtain such semantic paths reliably, we combine the semantic map learnt from the previous phase, with user...
activity distributions and co-location events between robot and user. Fusing the above information in a probabilistic framework, we are able to train the parameters of a Hidden Markov Model (HMM), which we then apply to infer the user’s semantic paths. It is worth noting that co-location events are only used for training the HMM; they are not used at the inference stage. This means that the system can learn to track the user thru rooms independently of whether the robot happens to be there. Further details on this part of the system are provided in Section V.

IV. SEMANTIC MAPPING

In this section we describe the first phase of our approach, in which the robot is able to create a semantic map on top of the metric map of the environment, by accumulating information on user activities over time during robot-user co-location events. We first introduce Bidirectional Long-Short Term Memory (BLSTM) neural networks and describe the proposed activity classification network architecture. Then, we describe the semantic mapping creation process.

A. Activity recognition

Bidirectional Long-Short Term Memory (LSTM) Recurrent Neural Networks (RNNs) have recently shown promising results when applied to the problem of human activity recognition [11], [32]. Inspired by these works, we started off by training a BLSTM network that uses raw acceleration and gyroscope data as input. However, the disadvantage of this approach is the vanishing gradient problem. In [14] Long Short-Term Memory networks (LSTMs) were introduced as a modified version of RNNs, in order to address the vanishing point problem. Through the inclusion of gating cells which allow the network to selectively store and forget past memories. The input gate \( g^i \) controls how the input enters into the contents of the memory cell for the current time-step. The forget gate, \( g^f \), determines when the memory cell should be emptied by producing a control signal in the range 0 to 1 which clears the memory cell as needed. The output gate \( g^o \) determines whether the contents of the memory cell should be used at the current time-step. \( g^c \) is the cell state vector.

\[
\begin{align*}
g^i &= \sigma(W^i * h_{t-1} + I^i * x_t) \\
g^f &= \sigma(W^f * h_{t-1} + I^f * x_t) \\
g^o &= \sigma(W^o * h_{t-1} + I^o * x_t) \\
g^c &= \tanh(W^c * h_{t-1} + I^c * x_t) \\
m_t &= g^i \odot m_{t-1} + g^o \odot g^c \\
h_t &= \tanh(g^c \odot m_{t-1})
\end{align*}
\]

where \( W^u, W^f, W^o, W^c \) are weight matrices and \( I^u, I^f, I^o, I^c \) are projection matrices. \( \sigma \) is the logistic sigmoid function. \( m_t \) is the internal state of the cell and \( h_t \) is the hidden vector.

LSTMs have been showed to be able to learn temporal behaviour and have been extensively used in many applications. Hence, they seem a natural choice for detection of complex activities from sequences of data that present a temporal component.

Bidirectional LSTMs (BLSTMs) [10] are a variant of LSTMs composed by one forward LSTM and one backward LSTM running in reverse on the data and with their features concatenated at the output layer. This enables information from both past and future to come together. BLSTMs have been found to perform better when dealing with small datasets.

A limit of RNNs is their tendency to overfit. Dropout can help to a certain extent, but it has been shown to fail when applied to recurrent layers. In [9] the authors suggested the use of dropout in LSTMs for approximate Bayesian inference. In the proposed variant, dropout is also used in the recurrent connections, and the same dropout masks are repeated at each time step for inputs, outputs, and recurrent layers.

Variational LSTMs have been shown to outperform the classic variant, while at the same time offering a useful Bayesian representation of the output, giving an estimate of the output uncertainty. However, to our knowledge they have not yet been explored in the context of human activity recognition.

In the variational variant Equation 1 becomes:

\[
\begin{align*}
g^i &= \sigma(W^i * (h_{t-1} \odot z_h) + I^i * (x_t \odot z_x)) \\
g^f &= \sigma(W^f * (h_{t-1} \odot z_h) + I^f * (x_t \odot z_x)) \\
g^o &= \sigma(W^o * (h_{t-1} \odot z_h) + I^o * (x_t \odot z_x)) \\
g^c &= \tanh(W^c * (h_{t-1} \odot z_h) + I^c * (x_t \odot z_x))
\end{align*}
\]
where \( z_r, z_h \) are random binary masks that remain constant at each step.

The other difference from standard LSTMs is that at prediction time the dropout remains active. Each prediction is repeated \( n \) times, in our case 50 times, and it is possible to compute the mean class prediction and the associated variance over the set of \( n \) samples, obtaining a prediction vector \( HAR \) (Human Activity Recognition), where each element \( i \) denotes the probability \( p[i] \) of activity \( i \) and the uncertainty \( \sigma[i] \) around it:

\[
HAR[i] = (HAR_p[i], HAR_\sigma[i])
\]

The ability to have an estimation of the uncertainty associated with the detection is crucial when including this information in a probabilistic framework.

### B. Semantic map inference

#### Topological mapping

As in [20], at the lower level a SLAM algorithm creates a grid map of the environment using the robot sensors. Using a template-based door detector [20] on laser distance data, the robot is able to group together multiple cells into individual rooms. We use the concept of room in a broad sense to denote both regular rooms and corridors. The aim of semantic mapping is to assign semantic categorical labels (e.g. kitchen, bathroom, corridor, etc.) to each cell in the grid.

**Detecting colocation events** Once the robot builds a grid map of the environment, it starts roaming thru it, and records any colocation events with users. In this section, we explain how to robustly detect colocation events and identify the user with whom the robot is colocated. For detecting humans, we use fusion of distance data from the laser range finder on board of the robot; we use open source code of an existing detector that learns to recognise human legs [28].

However, in our application we must ensure that the detected person is effectively the user wearing the smartwatch. To this end, we placed one BLE beacon onboard of the robot and measured the received signal strength at the smartwatch. On detecting a beacon, the smartwatch sends to the robot, the user identifier along with that user’s HAR (activity distribution) vector. Note that other methods based on Received Signal Strength (RSS) beyond BTLE could be used for identifying users, for example WiFi typically available on smartwatches.

When the robot detects a user and receives probabilistic activity data from that user, it triggers a colocation event. Figure 3 shows an example of the colocation detection while the user is approaching the robot.

**Semantic map updates**

Each cell \( c \) in the robot’s grid map is assigned a vector \( smap[c] \) indicating the probability that cell \( c \) belongs to a room of a particular type. We use the abbreviation ‘smap’ to refer to the semantic map. For example,

\[
\begin{align*}
\text{smap}[c] &= \begin{bmatrix}
0.20 & \rightarrow & \text{office} \\
0.40 & \rightarrow & \text{kitchen} \\
0.15 & \rightarrow & \text{bathroom} \\
0.35 & \rightarrow & \text{bedroom} \\
\vdots
\end{bmatrix}
\end{align*}
\]

Let \( smap[c]^r \) be the element of \( smap[c] \) that corresponds to a certain room type \( r \); for example \( smap[c]^{\text{kitchen}} \) is the current estimate of the probability that cell \( c \) is in the kitchen. At bootstrap, \( smap[c] \) is uniformly distributed over all room types.

On detecting a colocation event, the robot highlights a number of cells that are within its view, with the intention of updating their semantic map probabilities. Figure 4 shows the cells that are within the sensing range of the robot when it detects a person nearby. Note that if a robot is situated in a room and looks in the direction of the door, it ignores those cells that are beyond the door frame.

The probabilities of selected cells having different room types are then updated as follows.

\[
\text{smap}[c]^{r} := \text{smap}[c]^{r} \times \sum_{a \in \text{Activities}} p(r|a) \times HAR_p(a)
\]

where \( p(r|a) \) is the probability of being in a room given activity \( a \), and \( HAR_p(a) \) is the probability that the user is actually performing that activity. In practice this is implemented as a
The semantic map is updated after each robot-user colocation event. It can further be refined by taking into account that cells belonging to the same room should be of the same type. By averaging out the snap values of all cells in the same room we obtain a probabilistic semantic label for each room.

V. User Localisation

In this section we propose a simple graphical model for room-level localisation based on Hidden Markov Models. The model is based on the joint probability distribution between user location and activity. The states of the model represent semantic room types and the transitions represent the transition probability between different room types, e.g. from kitchen to bathroom.

The model alternates between two phases, depending on the predicted activity, namely a walking phase, and a stationary activity phase. If a series of walking activities are detected, the model estimates the length of the walking phase in seconds (this is possible since activities are detected at a constant rate) and treats it as a single walking event, representing a transition between two nodes.

Otherwise, if another activity is detected, the model updates the probability distribution of each node according to emission probabilities, as in a classical HMM.

Let \( p^t = (p_1^t, \ldots, p_n^t) \) be the probability vector for the current location at time \( t \), where \( n \) is total number of rooms. Each time a new activity is detected, the vector \( p^t \) is updated using one of the two rules discussed below.

**Walking Phase Update** We model the walking phase via a random variable \( w \) which contains information about the currently performed walking activity. Examples of possible interpretations for \( w \) are walking time, number of steps, walking distance, or even a part of a trajectory. In this work we consider the simple case that \( w \) represents the walking time between two stationary user activities.

Assuming \( w \) is a continuous random variable we have:

\[
   p_i^t = \int p(r^{t-1} = r_j) p(r^t = r_i | w, r^{t-1} = r_j) p(w) dw
\]

where we have assumed that \( W \) and \( r^{t-1} \) are statistically independent. The integral in the above formula, marginalises over the uncertainty on the walking random variable \( w \), whereas the sum marginalises over the uncertainty of the location at the previous step \( r^{t-1} \).

The term \( p(r^t = r_i | w, r^{t-1} = r_j) \) represents the likelihood of the transition from room type \( r_j \) to room type \( r_i \) via a walking event \( w \).

This formulation accounts for the uncertainty on the estimation of the walking times between rooms. For simplicity, we can evaluate the walking time \( w \) without uncertainty by estimating the duration of multiple contiguous walking activities. This results in the simpler formula:

\[
   p_i^t = \sum_{j=1}^{m} p(r^{t-1} = r_j) N(w; \mu_{ij}, \sigma_{ij})
\]

where \( \mu_{ij} \) and \( \sigma_{ij} \) is the mean and standard deviation of the time required to walk from a room type \( r_i \) to a room type \( r_j \).

In summary, the walking activity events are concatenated into a single walking event which acts as a control input in the HMM, and impacts the transition probability between different room types.

**Stationary Activity Phase Update** In the stationary activity phase, state probabilities are only updated using emission probabilities. The emission probability for a given room type represents the probability of observing an activity \( a \) given room type \( r \). The state probabilities are then updated as follows:

\[
   p_i^t = p_i^{t-1} \sum_{j=1}^{m} p(a^t = a_j | r^t = r_i) p(a^t = a_j)
\]

The factor \( p(a^t = a_j) \) is the probability of the user performing activity \( a_j \) at time step \( t \). It is the result of the activity prediction represented as \( HAR\_p(a_j) \) in Section IV-A.

Empirically, we found increased localisation accuracy by tweaking the above formula into:

\[
   p_i^t = p_i^{t-1} \sum_{j=1}^{m} p(a^t = a_j | r^t = r_i) p(a^t = a_j)(1 - \sigma_j^t)^2
\]

where the factor \((1 - \sigma_j^t)^2\) penalises the effect of activity predictions that show a high standard deviation. By setting \( \sigma_j^t \) to \( HAR\_\sigma[a] \) the model is able to embed the uncertainty estimation from the variational BLSTM (see Section IV-A).

**Training phase** Note that the conditional probability \( p(a^t = a_j | r^t = r_i) \) is learnt automatically before it is used within the HMM for localisation. This occurs during the colocation events between the robot and the user. Whenever they are both in room \( r_i \), the activity recognition module returns a vector \( HAR \) as discussed in Section IV-A. HAR vectors corresponding to the same room are averaged out in order to learn the conditional probability of activity given room.

VI. EXPERIMENTAL RESULTS

We implemented our neural network using the Keras library and Tensorflow as the optimization backend. The semantic mapping system is implemented using the Robot Operating System (ROS). The source code will be available online as well as the user activity dataset used in the experiments.

A. User activities

1) Data collection protocol: For training our network, we gathered inertial data from a set of 20 users (of ages between 24 and 60 (with \( \mu=31 \)). Users were given a smartswatch (Sony Smartwatch 3) to be worn on their right hand if right-handed or on the left if left-handed. We defined a list of complex daily activities typical of domestic environments. Each subject was
asked to perform the activities, one by one, based on his/her own interpretation and style. In order to sufficiently sample the continuous movement of non-transient actions, each subject was asked to perform each activity continuously for 60 seconds or more. We define the following list of 10 activities:

1) Washing dishes
2) Opening door
3) Dressing up
4) Drinking/eating
5) Washing hands
6) Idling
7) Using a PC/laptop
8) Brushing teeth
9) Walking
10) Writing

Two are simple activities (walking, idling), while the rest are complex activities that are typically performed very differently by different people and in different environments. 3 hours and 10 minutes of data were collected in total.

2) Training: We train our network architecture using standard back-propagation and the ADAM optimizer. For activity recognition the input of the network is a sequence of 3-axial acceleration data and 3-axial angular velocity data of fixed length. Since the sensors present different sampling rates (the accelerometer samples acceleration at ~ 100Hz, while the gyroscope samples at a lower ~ 30Hz), we oversample the gyroscope data in order to match that of the accelerometer, using piecewise cubic spline interpolation.

We experimentally found that a window size of 3s offers the best results for complex activity classification in most cases. This is due to the fact that these activities are composed by a series of movements that span over a longer time window, compared to classic activities such as walking, running, biking, etc. We divide the data into windows of 3s with an overlap of 50%. The data is subsampled to a frequency of 50 Hz and a median filter is applied on the raw data in order to smooth outlier measurements.

The optimal hyperparameters for the network were found using the Hyperas python package with TPE optimization and are reported in Table 1. $p_{W,1}$, $p_{U,1}$ and $p_{do}$ represent the dropout ratios for the $W$ weight matrices, for the $U$ weight matrices, and for the drop-out layer respectively. Note that the batch size is dependent on the hardware setup.

Figure 5 shows the classification results. The network achieves an accuracy of 87.5% on the test set. In order to validate the choice the proposed architecture, we also compared with three baselines: anon-variational LSTM, a non-variational BLSTM (i.e., dropout was disabled at prediction time), both using the same hyperparameters, and another non-recurrent deep method [6]. The LSTM and the BLSTM achieved an accuracy of 78% and 82% respectively. [6] achieved 82.5% accuracy.

B. Semantic mapping

We test the semantic mapping in both an office-like environment and a domestic environment. In our experiments, users are equipped with a smartwatch, connected via WiFi to the robot. The robot is a Turtlebot 2 equipped with a Microsoft Kinect camera. The robot is using the Kinect to simulate a laser range finder to localize in the map, to detect doors using a simple template matching algorithm available in ROS and to detect the user using a simple classifier for leg detection based on laser scans. As mentioned before, the camera is not used due to privacy concerns. The first scenario is an office-like environment, composed by a series of rooms and a corridor. We had access to the planimetry of the floor in the form of CAD files, but the robot could build a map beforehand by performing SLAM. In our experiment we are interested in mapping five rooms (lab, conference room, kitchen, office, bathroom). There is a sixth multi-purpose room in the center, but it is not included in the experiment since it is not represented by any particular set of activities. The setup for the experiment is shown in Figure 6. For the second scenario, a grid map was built autonomously by the robot beforehand using the gmapping ROS package.

The experiment lasted for a total of 30 minutes per user, with the robot and the user moving in the environment, entering various rooms and triggering colocation episodes, and the cumulative result is shown in Figure 7. It should be noted that in our experiments the robot was wandering autonomously from room to room in a randomized manner.

Some issues are visible in the resulting semantic maps. For instance, one door leading from the kitchen to the corridor was not correctly detected at first. This is due to the difficulty to tune the parameters of the door detector for different types of openings. This led to part of the corridor nearby the kitchen to be labelled as corridor. The resulting semantic map is somewhat sparse in certain areas, since there were
Fig. 6. The setup for the experimental tests during a colocation event, while the user is performing an activity. The user is wearing a smartwatch; the robot is using a Kinect camera for simulating a laser range finder.

Fig. 7. Resulting semantic map for the first scenario (activities only). The estimated topological and semantic maps are superimposed a CAD map. Each color of the map corresponds to a different room type (blue = corridor, red = lab, light red = office, yellow = kitchen, green = bathroom, cyan = common room). The topological map is represented by colored circles (each color represents a different room and red dots represents detected doors).

few colocation episodes. Over a longer period of time we can expect the map to become more complete. On the other hand, the probabilistic mapping procedure was able to cope with misclassified activities among the users, by smoothly updating the map probabilities over time.

Figure 9 reports the ratio of map cells identified as a particular room type for the five rooms in the first scenario. The values are computed as the ratio between the cells classified as a particular room type and the total number of cells in each room. Note that the final mapped area is dependent on the presence of furniture or obstacles and on the trajectory of the robot. The values in Figure 9(a) reflect the fact that only partial areas of each room have been mapped. For instance as the office was occupied by a desk and several chairs, the robot couldn’t reach the whole room.

In order to provide a baseline for semantic mapping we also show the result of semantic mapping using the visual place classification approach from [24]. The result is shown in Figure 8. In [24], a convolutional neural network based on AlexNet was pre-trained on the Places205 dataset [33] for place classification. The network takes RGB images in input from the Microsoft Kinect camera mounted on the robot. We only use the subset of the 205 place labels which are relevant to the testing environment (office, kitchen, conference room, corridor). It can be seen how the corridor class, absent from our method, is correctly classified by the network from [24], at the cost of a large number of false positives. No fine-tuning of the network was done.

Figure 11 shows the results of one run in a household composed by four rooms (bedroom, living room, kitchen, bathroom), while Figure 9(b) reports the ratio of map cells identified as a particular room type for the four rooms in the scenario. The experimental results show consistently accurate classifications.

C. User localisation

In this experiment we show how we can combine the semantic map obtained in the first phase and successive colocation events in order to learn the parameters of a simple graphical model for user localisation at room-level, independently from the robot. We perform these experimental tests in the same two scenarios of the previous experiment. Inertial data was collected from a test set of 5 users. We show the localisation results and compare them with the ground-truth location, which is obtained by placing BLE beacons in each room of interest in both scenarios.

The system first learns the correlation between room locations and activities, in the form of emission probabilities for the different activities given room types. This is done over a series of colocation events over time. Since the robot has access to the semantic maps from the previous experiment, it is able to learn the emission probabilities over time. The relation between the activities and the six semantic rooms considered is plotted in Figure 12. We expect that the activities performed

Fig. 11. Resulting semantic map for place classification in a domestic environment. Here red=bedroom, blue=living room, cyan=kitchen, green=bathroom. The map constructed by the robot is used here.

Fig. 12. Learned emission probabilities for activities performed in each room (office-like environment).

in rooms which are of the same type to be similar (e.g. lab and office), so in this experiment we combine the two room types. Notice that the opening door activity is not considered, as it is not related to a specific room, but to the transition between rooms. We use Laplace smoothing on the estimated transition probabilities. As the classes are somewhat unbalanced (e.g., people tend to spend most of the working day in the lab), the classification accuracy for each specific class is weighted by the number of samples in the class. The room-to-room distances used to estimate transition probabilities are obtained from the topological map built by the robot on top of the metric map.

We provide statistical results for the localisation module in Table II for both environments and averaged over a test set of 5 users, and we compare our graphical model with a baseline approach consisting of a trivial HMM implementation, where the transition and emission probabilities are the same as the proposed graphical model. It should be noted that for the office-like scenario we used 3s windows, while for the domestic scenario a window of 5s gave the best results. In Figure 10 we show the detected activities along with the predicted room locations for one user in the second scenario, for a duration of 30 minutes. The results show how the proposed model can outperform a classical HMM in our particular task.

VII. CONCLUSIONS

This work presented a framework that integrates assistive robots, that will be present in workplaces and households of the future, and consumer wearable devices, for sharing information between robots and users that benefit each other. In our scenario, a robot and the user coexist in a workplace or household. The robot creates a map using any sensor that can provide distance measurements, then it is able to navigate the environment using standard navigation algorithms. The user wears a smartwatch that continuously acquires inertial data. Whenever the robot and the user meet, user activities are used to build additional semantic layers on top of the map, representing room type probability. We propose the use of a variational bidirectional LSTM network for recognizing complex spatio-temporal activities from raw data, that keeps

|           | Precision | Recall | $f_1$ score |
|-----------|-----------|--------|-------------|
| Baseline HMM |           |        |             |
| Office-like | 0.8       | 0.71   | 0.75        |
| Domestic   | 0.8       | 0.75   | 0.77        |
| Proposed model |         |        |             |
| Office-like | 0.81      | 0.91   | 0.86        |
| Domestic   | 0.87      | 0.95   | 0.91        |

TABLE II   

PREDICTION ACCURACY OF USER LOCALISATION FOR BOTH SCENARIOS FOR THE PROPOSED MODEL AND A BASELINE HMM IMPLEMENTATION.

ACKNOWLEDGMENT

The whole framework probabilistic. Once a semantic map is available, raw data from the user’s wearable device can be used to detect room types. Over time, we train a room-based graphical model for room level localisation for the user even in the absence of the robot. In the model, nodes represent room types and transitions represent transitions between room types. This enables the robot to know the type of room the user is in at any time, for executing high-level tasks. Future work could be devoted to integrating a Pedestrian Dead Reckoning (PDR) algorithm into the localisation module. Another interesting extension would be to investigate active exploration strategies for the robot in order to maximize the chance of co-localization events. Finally, semantic user localisation could provide real-time context information to context-aware reasoning systems for supporting users without the need to instrument the environment, relying instead on mobile autonomous robots and wearable sensors.
