Abstract
Background: Bronchoscopic lung volume reduction (BLVR) using 1-way endobronchial valves (EBV) has become a guideline treatment in patients with advanced emphysema. Evidence from this minimally invasive treatment derives mainly from well-designed controlled trials conducted in high-volume specialized intervention centres. Little is known about real-life outcome data in hospitals setting up this novel treatment and which favourable conditions are required for a continuous successful program. Objectives: In this study, we aim to evaluate the eligibility rate for BLVR and whether the implementation of BLVR in our academic hospital is feasible and yields clinically significant outcomes. Method: A retrospective evaluation of patients treated with EBV between January 2016 and August 2019 was conducted. COPD assessment test (CAT), forced expiratory volume in 1 s (FEV\textsubscript{1}), residual volume (RV), and 6-min walking test (6MWT) were measured at baseline and 3 months after intervention. Paired sample t tests were performed to compare means before and after intervention. Results: Of 350 subjects screened, 283 (81\%) were not suitable for intervention mostly due to lack of a target lobe. The remaining 67 subjects (19\%) underwent bronchoscopic assessment, and if suitable, valves were placed in the same session. In total, 55 subjects (16\%) were treated with EBV of which 10 did not have complete follow-up: 6 subjects had their valves removed because of severe pneumothorax (n = 2) or lack of benefit (n = 4) and the remaining 4 had missing follow-up data. Finally, 45 patients had complete follow-up at 3 months and showed an average change ± SD in CAT −4 ± 6 points, FEV\textsubscript{1} +190 ± 140 mL, RV −770 ± 790 mL, and +37 ± 65 m on the 6MWT (all p < 0.001). After 1-year follow-
Implementation of Bronchoscopic Lung Volume Reduction

Introduction

Patients suffering from severe emphysema experience chronic dyspnoea and have impaired exercise tolerance and poor health-related quality of life. Despite optimal pharmacological therapy, smoking cessation, pulmonary rehabilitation (PR), and long-term oxygen therapy, the majority of the patients remain significantly disabled. Therefore, treatment is often focused on symptom relief and disease control [1].

Lung volume reduction surgery (LVRS) can provide clinical benefits in selected patients with predominantly upper lobe disease and low exercise capacity [2]. However, this procedure is associated with increased perioperative morbidity and mortality [3]. Similar to LVRS, endobronchial valve (EBV) treatment aims to reduce lung hyperinflation, by selectively targeting less functional areas of the lung with 1-way valves inducing atelectasis and is considered minimally invasive with lower rates of mortality and major postprocedural complications [4]. To date, there is increasing evidence that patients with advanced emphysema can experience meaningful improvements in lung function, dyspnoea, exercise capacity, physical activity, and quality of life after bronchoscopic lung volume reduction (BLVR) treatment with EBV [4–9], which were still present after 1-year follow-up [10, 11]. The 2020 Report from the Global Initiative for Chronic Obstructive Lung Disease (GOLD) upgraded the level of evidence for EBV treatment to the highest evidence rating and supports the use of EBV treatment as standard care for select patients with advanced emphysema [1].

However, most evidence for the effectiveness of EBV treatment is available from large multi-centre randomized controlled trials conducted in centres with extensive experience in bronchoscopic interventions. Therefore, this study describes the patient selection, real-world clinical outcome data, and experiences in implementing EBV treatment in an academic hospital in the Netherlands with no prior experience in BLVR.

Conclusion: Implementing BLVR with EBV is feasible and effective. Only 16% of screened patients were eligible, indicating that this intervention is only applicable in a small subset of highly selected subjects with advanced emphysema, and therefore a high volume of COPD patients is essential for a sustainable BLVR program.

Materials and Methods

We performed a retrospective evaluation of all COPD patients screened for potential EBV treatment between January 2016, the start date of the BLVR programme, and August 2019 in the Maastricht University Medical Centre+, the Netherlands. Screened subjects were recruited from our own hospital clinic, local referral hospitals, and a tertiary PR clinic specialized in complex COPD affiliated with our hospital (CIRO, Horn, the Netherlands). Candidates underwent a stepwise evaluation from chart examination, extensive pulmonary function testing (PFT), and imaging to case discussion in a multidisciplinary team consisting of chest physicians, chest surgeon, and specialized chest radiologists, as patients became more eligible for BLVR.

Subjects were considered eligible for BLVR if they met the criteria (shown in Table 1) as were recommended in the expert recommendation [12]. The criteria were indicators for patient selection and not stringently applied, thus if a good target lobe was present in heterogeneous emphysema, a FEV1 below 20% was accepted. A high-resolution computed tomography was performed to assess the extent and distribution of emphysema and fissure completeness and to rule out contraindications for valve placement, like severe airway pathology or suspected nodules. A quantitative CT analysis (StratX© software; PulmonX, Inc.) was performed to (1) quantify the severity of emphysema in each lobe by measuring the percentage of volume under a predefined density threshold of −910 Hounsfield units (HU) and below −950 HU [13, 14], (2) quantify the lobar volume, and (3) examine the fissure integrity. In homogeneous emphysema, perfusion scintigraphy was performed, and if a target lobe showed clear diminished perfusion compared to the ipsilateral lobe, BLVR was considered.

Screening and consultation were done by dedicated chest physicians with experience in COPD and affinity with BLVR. Potential candidates were informed of the diagnostic results and treatment

Table 1. Eligibility and ineligibility criteria for BLVR

| Eligibility criteria                                      |
|---------------------------------------------------------|
| Symptomatic COPD (mMRC ≥2)                              |
| 40–75 years of age                                      |
| FEV1 ≥20% and ≤50% predicted                            |
| RV ≥175% predicted                                      |
| RV/TLC >0.55                                           |
| Emphysema on HRCT, quantitative analysis                |
| Optimal pharmacological inhalation                       |
| Smoking cessation at least for 6 months                 |

| Ineligibility criteria                                   |
|---------------------------------------------------------|
| Unfit for intervention                                   |
| Severe chronic respiratory failure                       |
| Chronic bronchitis                                      |
| Severe comorbidities                                    |
| Extensive airway pathology on HRCT                       |

advice given by the multidisciplinary team. Finally, shared decision-making between physician and candidate was the basis to perform BLVR. Prior to the intervention, subjects were stimulated to undergo an 8-week tertiary PR programme.

The intervention was performed under general anaesthesia in intubated subjects with mechanical ventilation support. Interlobar collateral ventilation was measured using the Chartis System® (Pulmonx Inc., Redwood City, CA, USA). Only Zephyr valves (PulmonX Inc., Redwood City, CA, USA) were used in our hospital. No antibiotic or corticosteroid prophylaxis was administered before BLVR. Treated subjects stayed admitted in the hospital for 5 days and were periodically followed up in our clinic after discharge.

Periodically, consultation was sought with a pulmonologist from the University Medical Centre Groningen, the Netherlands, for advice on BLVR. COPD assessment test (CAT), PFT including spirometry, body plethysmography, and 6-min walking test (6MWT) were performed at baseline and 3 months after the intervention. Outcomes were compared to minimal clinically important difference of 2 points on CAT score [15], 100 mL change in FEV₁ [16], 25 m on 6MWT [17], and reduction of 430 mL in RV [18].

Results

During the study period, a total of 350 subjects with advanced COPD were screened for BLVR. Most subjects, 283 (81%), had multiple characteristics that made them unsuitable (shown in Fig. 1). The most frequent contraindications were radiologic features, namely, homogeneous emphysema distribution and the absence of a target lobe in 66 cases (18.9%). Second, PFT not meeting the inclusion criteria was an important contraindication in 64 subjects (18.2%).

In a significant number of subjects (n = 30), shared decision-making between physician and candidate resulted in not preferring BLVR. Most of these subjects were fearful of potential complications, mainly pneumothorax. One subject had such a significant improvement in exercise capacity and symptoms after PR that inclusion criteria for BLVR no longer applied.

The remaining 67 subjects (19%) underwent bronchoscopic assessment, and if suitable, valves were placed in the same session. In 12 subjects, no intervention was performed due to collateral ventilation (n = 11), or unexpected endobronchial lesion (n = 1) revealed during bronchoscopy. Fifty-five subjects (16%) were treated with EBV. Ten did not have a complete follow-up at 3 months, including 6 subjects who had their valves removed because of severe pneumothorax (n = 2) or lacking treatment benefit (n = 4) and the remaining 4 subjects had missing data at follow-up. So finally, complete baseline and follow-up data were available in 45 subjects. The group had a mean age of 63 years with a mean FEV1, RV, and DLCO, of, respectively, 28%, 240%, and 37% of predicted. Baseline and follow-up values are presented in Table 2. The mean changes in outcomes are shown in Figure 2.

| Characteristics | Baseline | 3 months | p value |

Data are shown as mean or as percentage ± SD and age in years. L, litre; TLC, total lung capacity; RV, residual volume; DLCO, diffusing capacity for carbon monoxide; 6MWD, 6-minute walk distance; HU, Hounsfield units; mL, millilitre. Response rate = percentage of subjects reaching minimal clinically important difference. † Eight CAT scores were missing resulting in 37 pairs to compare. ‡ One quantitative CT analysis was missing.
Thirty-three (73%) of the 45 BLVR patients underwent an 8-week internal PR at CIRO within 1 year before the intervention. There was no difference in outcome between the subjects who did or did not undergo PR before BLVR.

After 1-year follow-up, 34 of the 45 (76%) treated subjects had their EBV in situ. The most prominent reason for removal of EBV was loss of benefit mostly due to granulation tissue (n = 5). Other reasons for removal were recurrent pneumonia (n = 2), torsion of the bronchus (n = 1), lack of benefit (n = 1), and diffuse endobronchial bronchitis reaction (n = 1). One patient died within 1 year after BLVR (not-BLVR related, acute intestinal bleeding). Of the 34 patients with EBV in situ at 1 year, 5 did not have a follow-up visit mostly due to not attending the visit, resulting in 29 patients with 1-year pulmonary function data; in 2 patients, RV was not performed, and in 7 patients, the 6MWD was missing. After

**Table 3.** Postprocedural complications in the 55 subjects treated with BLVR during the first 3 months

| Complication                                             | N = 55 |
|---------------------------------------------------------|--------|
| Pneumothorax                                            | 5 (9.1)|
| Postprocedure COPD exacerbation                         | 15 (27.3)|
| Haemoptysis                                             | 2 (3.6)|
| Torsion of the bronchus                                 | 2 (3.6)|
| Pneumonia or airway infection requiring antibiotics      | 17 (30.9)|
| Valve expectoration                                     | 1 (1.8)|
| Temporarily O₂ supplementation                          | 9 (16.4)|
| Mortality at 3 months                                   | 0 (0)  |

Data are shown as n (%). Counts reflect number of subjects reporting the specific complication. Subjects could have multiple complications. BLVR, bronchoscopic lung volume reduction; COPD, chronic obstructive pulmonary disease.
1 year, the mean change in FEV\textsubscript{1} was $+101 \pm 176$ mL ($p < 0.05$), RV $-527 \pm 842$ mL ($p < 0.05$), and 6MWD $+7 \pm 55$ m ($p > 0.05$).

The most common adverse events, represented in Table 3, were airway infections requiring antibiotics and post-intervention COPD exacerbations. Slightly over half of the subjects (54.5%) experienced at least 1 complication of which most were easily manageable and not severe. No mortality occurred in the first 3 months after intervention. The pneumothorax rate in our cohort was 9%, and all were treated with a pleural chest catheter. If necessary, single or complete valve removal was performed to allow expansion of the collapsed lung, which was the case in 6 subjects. Nine subjects required temporarily oxygen supplementation during hospitalization or after discharge but could be stopped before the first follow-up visit and was mostly attributed to COPD exacerbation.

Discussion

We report our experience with the implementation and results of BLVR using 1-way valves in an academic hospital. Only 16% of the severe COPD subjects in our cohort were eligible for EBV, indicating that this intervention is only applicable in a small subset of highly selected subjects with advanced emphysema. Therefore, a high volume of COPD patients is essential for a sustainable BLVR program.

Furthermore, outcomes at 3 months in real-life setting indicate that implementation is feasible and safe and that treated subjects demonstrate clinical meaningful improvements. At 12 months, the results are less pronounced.

Strict patient selection is crucial in achieving beneficial results and keeping the postprocedural morbidity and mortality rate low. Some literature exists on studying reasons for not receiving interventional treatment in severe COPD patients in real-life setting. Our results indicate that radiological features such as lack of or homogeneous emphysema and the inability to identify a good target lobe were the main reasons of denying treatment, followed by insufficient hyperinflation and unsuitable clinical condition. This is in line with previous reports; however, eligibility proportions are variable. May et al. [19] described in a single-centre retrospective cohort of 138 potential candidates an eligibility rate of 27.5%, though different BLVR techniques (EBV, coils, and vapour) were used, therefore probably causing a higher acceptance for intervention when compared to EBV alone. A recent study by Welling et al. [20] reported a selection rate of 19% out of 1,500 referrals for BLVR, but also different interventions were available. The most common reported contraindication in that study was lack of appropriate target lobe and unsuitable COPD phenotype. A specialized pulmonary intervention centre in Germany evaluated the reason for not performing lung volume reduction in 115 patients and reported incomplete fissures and absence of proper target lobe as the main contraindications with an eligibility rate of 14% [21].

Interestingly, in our centre, a significant proportion of patients (8.6%) were not treated based on shared decision-making between chest physician and patient, when advantages and disadvantages were discussed in detail. Some of these patients were fearful of potential complications. Additionally, screening for BLVR in COPD patients not specifically referred for this treatment, as was done during the baseline assessment for PR, could also be an explanation. It is reasonable to assume that most patients referred to a centre for BLVR already decided that, if eligible, are willing to undergo BLVR. This in contrary to when BLVR is one of the potential options in an assessment specified for PR. Shared decision-making has not been addressed as a major reason for non-treatment in previous studies.

The benefits from EBV treatment in this report are, in general, consistent with other real-world efficacy studies [11, 22]. However, treatment results vary due to differences in inclusion criteria, primary outcome, and follow-up duration.

Skowasch et al. [22] reported in a prospective, observational, single-arm multi-centre trial in Germany at 6-month follow-up a mean improvement of $+100$ mL in FEV\textsubscript{1} and an RV reduction of $-0.42$ L which are just around the minimal clinically important difference cutoff values. Gompelmann et al. [11] reported in a retrospective cohort with a follow-up period up to 3 years efficacy with gradual decline of the lung function parameters over time. This decline is also demonstrated in our report and could be due to progression of COPD or loss of benefit of the EBV. Randomized controlled trials showed in general more pronounced outcomes [4, 6, 7]. Klooster et al. [6] reported in the STELVIO trial, a single-centre randomized controlled study, an average increase in FEV\textsubscript{1} of 161 mL and 6MWD of 60 m at 6 months in the intention-to-treat population. Criner et al. [4] reported in a large multi-centre trial in patients with heterogeneous emphysema, sustainable outcomes after 12 months of follow-up.
During the implementation of our BLVR, we were reserved about treating patients with homogeneous emphysema, since outcomes of homogeneous patients were not well reported, and benefit was mainly described for patients with a heterogeneous distribution of emphysema. This approach changed in some degree with the IMPACT study published late 2016 [7]. The trial reported positive 3-month outcome of EBV therapy in patients with homogeneous emphysema, although the effects appeared smaller in comparison with heterogeneous emphysema-treated patients.

The most common complication after BLVR in our cohort was airway infection requiring antibiotics. The cause of this high prevalence is not known and could be due to not administering prophylactic antibiotics. Another explanation could be the careful approach in the start-up phase, when antibiotics were sometimes started out of caution when patients reported increased sputum or cough after the intervention. The pneumothorax incidence was 9.3%, which is at the lower end of reported rates in the different trials (8–34%) [4–8]. Pneumothorax can also be used as a surrogate marker for achieving atelectasis, since the complication is mostly due to overexpansion of the ipsilateral untreated lobe. Pneumothorax was treated according to expert statement by Valipour et al. [23] and mostly required only chest tube drainage. Furthermore, new insights into the risk factors for pneumothorax became available [24] during our start-up phase, including para-septal emphysema, pleura-adhesion, or extreme large volume of the target lobe. These features are now mostly avoided. Since severe pneumothorax with persistent air leakage could need surgical intervention, in-hospital thoracic surgery facilities are advisory. Overall, it has been reported that the complication rate is higher in treated patients compared to the standard of care group, but only directly in the first 45 days after treatment; after this period, the frequency of complications was comparable between groups, even a tendency to fewer exacerbations, but this did not reach statistical significance [4].

A limitation of this study is that it is single centre, retrospective, and has limited length of complete follow-up. Also, not including the lost to follow-up subjects in the analysis gives a slightly overestimation of the reported outcomes.

Additionally, there is a lack of comparison with a control group. However, the strength is its real-life background without a strictly controlled research setting, which could make it more extrapolatable to the everyday practice.

Here, we discuss the lessons learned during our implementation process and the conditions necessary for a durable BLVR program. First, as many patients need to be screened and discussed for potential treatment, a dedicated COPD clinic seems to be important with anchoring as a regional referral centre maintaining a certain flow of patients to build up and maintain expertise. When starting up a BLVR program, a clear protocol of the patient selection, the intervention, and the clinical follow-up is key for self-evaluation of achieved results. A multidisciplinary approach and discussion, including the managing physician, the interventionist, and a committed chest radiologist, is needed. In addition, close contact with a high-volume experienced treatment centre to discuss the eligibility of more complex cases and complication management has been very helpful during our implementation phase. Availability of thoracic surgery is important for complication management but also for integration with an LVRS program. With more dedicated emphysema imaging, more subjects eligible for lung volume surgery are identified. In addition, subjects with late lobe re-inflation after valve treatment because of, e.g., granulation tissue and with an initial good response might be good candidates for a surgical intervention [25]. Finally, a good alliance with a PR centre including a thorough assessment and integrated personalized program is recommended to optimize the patients before the intervention. However, if PR before BLVR is the best sequence or better results can be achieved when PR is planned after the intervention is not known and is currently being investigated in the SolVE-trial (clinicaltrials.gov NCT03474471).

In conclusion, implementing BLVR with EBV is feasible, safe, and effective in start-up centres. This intervention is only applicable in a small subset of highly selected patients with advanced emphysema, indicating that a large flow of COPD patients is necessary for a sustainable program.
