Principal components of dark energy with SNLS supernovae: 
the effects of systematic errors

We study the effects of current systematic errors in Type Ia supernova (SN Ia) measurements on dark energy (DE) constraints using current data from the Supernova Legacy Survey (SNLS). We consider how SN systematic errors affect constraints from combined SN Ia, baryon acoustic oscillations (BAO), and cosmic microwave background (CMB) data, given that SNe Ia still provide the strongest constraints on DE but are arguably subject to more significant systematics than the latter two probes. We focus our attention on the temporal evolution of DE described in terms of principal components (PCs) of the equation of state, though we examine a few of the more common, simpler parametrizations as well. We find that the SN Ia systematics degrade the total generalized figure of merit (FoM), which characterizes constraints in multi-dimensional DE parameter space, by a factor of two to three. Nevertheless, overall constraints obtained on more than five PCs are very good even with current data and systematics. We further show that current constraints are robust to allowing for the finite detection significance of the BAO feature in galaxy surveys.

I. INTRODUCTION

Since the discovery of the accelerating universe in the late 1990s [1, 2], a tremendous amount of effort has been devoted to improving measurements of dark energy (DE) parameters. As constraints on these parameters improved, controlling the systematic errors in measurements became critical for continued progress. The systematics come in many flavors, including a multitude of instrumental effects and astrophysical effects.

Type Ia supernovae (SNe Ia) were used to discover DE and still provide the best constraints on DE. The advantage of SNe Ia relative to other cosmological probes is that every SN provides a distance measurement and therefore some information about DE. More recently, SN Ia observations have been joined by measurements of baryon acoustic oscillations (BAO), which provide exceedingly accurate measurements of the angular diameter distance in redshift bins. Cosmic microwave background (CMB) anisotropies come mostly from high redshift and are thus not particularly effective in probing DE, but they do provide one measurement of the angular diameter distance to redshift \( z \approx 1100 \) very accurately. Galaxy clusters also constrain DE usefully, while weak gravitational lensing is expected to become one of the most effective probes of DE in the near future. For recent comprehensive reviews of DE probes, see [3, 4].

In this work, we are interested in studying the effect of SN Ia systematics on DE constraints by including the covariance of measurements between different SNe. The covariance includes primarily systematic errors, and for the first time it has been quantified in depth by Conley et al. [5]. Including the effects of the systematic errors, represented by nonzero covariance, weakens the overall constraints on model parameters. Here we wish to explore the effect of systematic errors for general models of DE described by a number of principal components (PCs) of the equation of state, though we first consider these effects for simpler, more commonly used descriptions of the DE sector. We choose to combine the SN Ia data with BAO and CMB measurements and estimate the effects of current systematic errors in SN Ia observations. We then proceed to study another systematic concern that is particularly relevant for BAO: whether the finite significance of the detection of the BAO feature in various surveys, when taken into account, weakens the constraints imposed on DE parameters.

While we closely follow the accounting for the SN Ia systematics from Conley et al. [5], we note that several other analyses have considered the effect of SN systematics. However, most of these analyses only studied the effects of the systematic errors on the constant equation of state (e.g. [5–8]) or included the additional parameter \( w_a \) to describe the variation of the equation of state with time (e.g. [9]). Notable exceptions are studies by Davis et al. [10] and Rubin et al. [11], which considered a number of specific DE models with non-standard behavior, and Amanullah et al. [12] and Suzuki et al. [13], which parametrized the DE density in several redshift bins. Here our goal is to go beyond any specific models and study the effects of systematic errors in current data on DE constraints in the greatest generality possible. While a truly model-independent description of the DE sector is of course impossible, a description of the expansion history in terms of 10 or so parameters
— which we adopt in this paper — comes close\footnote{We do not, however, consider allowing departures from general relativity; doing so would further generalize the treatment.}. In this sense, our paper complements the recent investigations by Mortonson et al.\footnote{Throughout the analyses in this paper, we actually marginalize analytically over a model with two distinct \( M \) values, where a mass cut of the host galaxy dictates which \( M \) value applies (here we use a mass cut of \( 10^{10} M_\odot \)). This is meant to correct for host galaxy properties and is empirical in nature (see text and Appendix C of \cite{5}). For simplicity, we suppress mention of the second \( M \) parameter.} (see also \cite{16,21}), which studied constraints on very general descriptions of DE using (a slightly different set of) current data but without specific study of the effects of systematic errors.

The paper is organized as follows. In Sec. II we describe the SN Ia, BAO, and CMB data (and for BAO and CMB, the distilled observable quantities) that we use in our analysis. In Sec. III we discuss useful parametrizations of DE and compare constraints on the DE parameters with and without systematic errors included in the analysis. In Sec. IV we investigate the effects of the finite detection significance of the BAO feature in galaxy surveys on the cosmological parameter constraints. In Sec. V we summarize our conclusions.

## II. DATA SETS USED

We begin by describing the data sets used in this analysis. We have used three probes of DE: SNe Ia, BAO and CMB anisotropies.

### A. SN Ia Data and Covariance

Although SNe Ia are not, of course, perfect standard candles, it has long been known that there exist useful correlations between the peak apparent magnitude of a SN Ia and the \textit{stretch}, or broadness, of its light curve (simply put, broader is brighter). The peak apparent magnitude is also correlated with the color of the light curve (bluer is brighter). We therefore model the apparent magnitude of a SN Ia with the equation \footnote{Recent work has concentrated on estimating correlations between measurements of individual SN Ia magnitudes. A complete covariance matrix for SNe Ia includes all identified sources of systematic error in addition to the intrinsic scatter and other sources of statistical error. The \( \chi^2 \) statistic is then given by}

\[
m_{\text{mod}} = 5 \log_{10} \left( \frac{H_0}{c} d_L \right) - \alpha_s(s-1) + \beta_c C + M, \tag{1}\]

where \( d_L \) is the luminosity distance, \( \alpha_s \) is a nuisance parameter associated with the measured stretch \( s \) of a SN Ia light curve, and \( \beta_c \) is a nuisance parameter associated with the measured color \( C \) of the light curve. The absolute magnitude of a SN Ia is contained within the constant magnitude offset \( \mathcal{M} \), which is considered yet another nuisance parameter.

Recent work has concentrated on estimating correlations between measurements of individual SN Ia magnitudes. A complete covariance matrix for SNe Ia includes

| Source | \( N_{SN} \) | Range in \( z \) |
|--------|--------------|----------------|
| Low-z  | 123          | 0.01 - 0.1     |
| SDSS   | 93           | 0.06 - 0.4     |
| SNLS   | 242          | 0.08 - 1.05    |
| HST    | 14           | 0.7 - 1.4      |

TABLE I. Summary of SN Ia observations included in this analysis, showing the number of SNe included from each survey and the approximate redshift ranges.

Recently Conley et al.\footnote{Recently Conley et al.\cite{5} determined covariances between SN Ia measurements from the Supernova Legacy Survey (SNLS). The SN compilation and covariance matrix that resulted from this work will be used in this analysis. The SNLS compilation consists of 472 SNe Ia, approximately one half of which were detected in the SNLS, while the rest originated from one of three other sources. These four main sources are summarized in Table I and illustrated in the Hubble diagram of Fig. 1. The low-redshift (Low-z) SNe actually come from a variety of samples as discussed in Conley et al.\cite{5}.} determined covariances between SN Ia measurements from the Supernova Legacy Survey (SNLS). The SN compilation and covariance matrix that resulted from this work will be used in this analysis. The SNLS compilation consists of 472 SNe Ia, approximately one half of which were detected in the SNLS, while the rest originated from one of three other sources. These four main sources are summarized in Table I and illustrated in the Hubble diagram of Fig. 1. The low-redshift (Low-z) SNe actually come from a variety of samples as discussed in Conley et al.\cite{5}.

The complete covariance matrix from\footnote{The diagonal (statistical-only) part of the covariance matrix between the SNe. Given a value for \( \chi^2 \), we assume that the likelihood of a set of cosmological parameters is Gaussian, so that \( L(p) \propto e^{-\chi^2/2} \).} can be written most usefully as the sum of two separate parts, a diagonal part consisting of typical statistical errors and an off-diagonal systematic part. The off-diagonal piece includes some correlated errors which are considered statistical in\footnote{The diagonal (statistical-only) part of the covariance matrix includes some correlated errors which are considered statistical in\cite{5} (since they can be reduced by including more observations), but here we disregard the distinction and group these errors with the actual systematic errors, which also lead to off-diagonal covariance elements. This simplification is reasonable because the correlated statistical errors are small compared to the (correlated) systematic errors. The diagonal (statistical-only) part of the covariance ma-} (since they can be reduced by including more observations), but here we disregard the distinction and group these errors with the actual systematic errors, which also lead to off-diagonal covariance elements. This simplification is reasonable because the correlated statistical errors are small compared to the (correlated) systematic errors. The diagonal (statistical-only) part of the covariance ma-
systematic terms are combined to produce submatrices diagonal systematic covariance matrix, where different varying the errors (recomputing the covariance matrix) tion of Note that even the diagonal covariance matrix is a func-
ties. The solid black line represents the best fit to the data. 

A similar equation can be used to construct the off-diagonal systematic covariance matrix, where different systematic terms are combined to produce submatrices which are then added together with specified values for \( \alpha_s \) and \( \beta_c \), as above. The elements of the systematic covariance matrix (see [5] for more details) are calculated using the equation

\[
C_{ij}^{sys} = \sum_{k=1}^{K} \left( \frac{\partial m_{mod,i}}{\partial S_k} \right) \left( \frac{\partial m_{mod,j}}{\partial S_k} \right) (\Delta S_k)^2, \tag{5}
\]

where the sum is over the \( K \) systematics \( S_k \), \( \Delta S_k \) is the size of each term (for example, the uncertainty in the zero point), and \( m_{mod} \) is defined in Eq. (1). Then the full covariance matrix is simply given by

\[
C^{full} = D^{stat} + C^{sys}. \tag{6}
\]

A plot of the full covariance matrix (constructed using flat \( w = \text{const} \) model best-fit values \( \alpha_s = 1.43 \) and \( \beta_c = 3.26 \)) is shown in Fig. 2.

B. BAO and CMB data

To produce the combined constraints in this paper, we include information from both BAO and the CMB in addition to the SN data. In each case, we choose for simplicity distilled quantities which depend only on \( \Omega_M \), \( \Omega_{\Lambda} \), \( \Omega_K \), and a parametrized \( w(z) \).

For BAO, we compare the theoretical prediction for the acoustic parameter \( A(z) \) with the measured value, where we define (see Eisenstein et al. [28])

\[
A(z) = \left[ \frac{r^2(z)}{H(z)} \right]^{1/3} \frac{\sqrt{\Omega_M H_0^2}}{cz}. \tag{7}
\]

We combine recent measurements of \( A(z) \) at different effective redshifts, using data from the 6dF Galaxy Survey [27], the Sloan Digital Sky Survey (SDSS) Data Release 7 (DR7) [28], the WiggleZ survey [29, 30], and the SDSS Baryon Oscillation Spectroscopic Survey (BOSS) [31, 32]. The measured values are summarized in Table I.

A plot of the measured values and their uncertainties superimposed on an \( A(z) \) curve (Fig. 3) suggests that there is no significant tension between the measurements. Note that the SDSS DR7 measurements at \( z = (0.2, 0.35) \) are correlated with correlation coefficient 0.337. The WiggleZ measurements are correlated with coefficient 0.369 for the pair \( z = (0.44, 0.6) \) and coefficient 0.438 for \( z = (0.6, 0.73) \). Ignoring the relatively small overlap in survey volume between SDSS DR7 and the BOSS sample, we expect all other pairwise correlations to be zero. We compute \( \chi^2 \) in the usual way for correlated measurements, as in Eq. (2).

Nearly all of the sensitivity of the CMB to DE comes from the measurement of an angle at which the sound horizon at \( z \approx 1100 \) is observed (e.g. [33]). This measurement in turn determines the angular diameter distance to recombination with the physical matter quantity, \( \Omega_M h^2 \), essentially fixed. The latter quantity is popularly known as the CMB shift parameter \( R \) and is defined as

\[
R \equiv \sqrt{\frac{\Omega_M H_0^2}{c}} r(z_\ast), \tag{8}
\]
FIG. 2. Left panel: correlation matrix obtained from the complete covariance matrix $C^\text{full}$, sorted first by survey and then by redshift within each survey. Right panel: same, but using only the systematic covariance matrix $C^\text{sys}$. In both cases we assume $\alpha_s = 1.43$ and $\beta_c = 3.26$, the best-fit values for the flat $w = \text{const}$ model. The right panel is similar to Fig. 12 from [5], but we repeat it here and show the full covariance (left panel) for completeness.

| Sample | $z_{\text{eff}}$ | $A_0(z_{\text{eff}})$ |
|--------|-----------------|------------------------|
| 6dFGS  | 0.106           | 0.526 ± 0.028          |
| SDSS DR7 | 0.20           | 0.488 ± 0.016          |
| SDSS DR7 | 0.35           | 0.484 ± 0.016          |
| WiggleZ | 0.44           | 0.474 ± 0.034          |
| BOSS   | 0.57            | 0.444 ± 0.014          |
| WiggleZ | 0.60           | 0.442 ± 0.020          |
| WiggleZ | 0.73           | 0.424 ± 0.021          |

TABLE II. Summary of measurements of distilled BAO parameter $A(z)$. We show the survey from which the measurement comes, the effective redshift of the survey (or its sub-sample), and the measured value $A_0$.

where $z_*=1091.3$ is the redshift of decoupling as measured by WMAP7 [34] and $r(z)$ is the comoving distance to redshift $z$. We take the measured value of $R$ to be the value determined by WMAP7, $R_0 = 1.725 \pm 0.0184$ [34]. We compute $\chi^2$ in the usual way, comparing this measured value of $R$ with the theoretical prediction.

Calculating the combined SN, BAO, and CMB likelihood is now a simple task. We define $L_{\text{comb}} \propto e^{-\chi_{\text{tot}}^2/2}$, where $\chi_{\text{tot}}^2 = \chi_{\text{SN}}^2 + \chi_{\text{BAO}}^2 + \chi_{\text{CMB}}^2$.

FIG. 3. Measured values of $A(z)$ and their (diagonal-only) uncertainties for each effective redshift. The black curve shows $A(z)$ for a model that fits the data points well, and the parameters for this model are given in the legend.

C. Parameter constraint methodology

We use two alternate codes to produce our constraints. For the basic constraints, including the constant equation of state of DE or the $(w_0, w_a)$ description, we use a brute-force search which computes likelihoods over a grid of values of $\sim 5$ parameters (listed below).

Alternatively, we developed a new Markov Chain Monte Carlo (MCMC; e.g., see [35, 36]) code to determine DE parameter constraints and figures of merit (FoMs) for the general ($\sim 13$ parameters) PC description. The MCMC procedure is based on the Metropolis-Hastings algorithm [37, 38]. From the likelihood $L(x|\theta)$ of the data $x$ given each proposed parameter set $\theta$, Bayes’ Theorem tells us that the posterior probability distribution
of the parameter set given the data is
\[ P(\theta|x) = \frac{L(x|\theta)P(\theta)}{\int L(x|\theta)P(\theta) \, d\theta}, \] (9)
where \( P(\theta) \) is the prior probability density. The MCMC algorithm generates random draws from the posterior distribution. We test convergence of the samples to a stationary distribution that approximates \( P(\theta|x) \) by applying a conservative Gelman-Rubin criterion \cite{39} of \( R - 1 \lesssim 0.03 \) across a minimum of four chains for each model class. We use the getdist routine of the CosmoMC code \cite{40,41} to process the resulting chains; getdist bins the chains and then smoothes the binned distribution of counts by convolution with a multidimensional Gaussian kernel.

We verified that the two codes give results that are in excellent agreement in several relevant cases, e.g. constraints in the \( \Omega_M-w \) or \( w_0-w_a \) plane.

### III. RESULTS: EFFECTS OF THE SYSTEMATICS

#### A. Preliminaries

Before beginning our discussion of systematics, we briefly consider the vanilla ΛCDM cosmology, where \( w = -1 \). The cosmological parameters describing the expansion rate are matter and cosmological constant densities relative to critical, \( \Omega_M \) and \( \Omega_\Lambda \). Including the nuisance parameters, the total parameter set is
\[ p_i \in \{\Omega_M, \Omega_\Lambda, M_t, \alpha_s, \beta_c\}. \] (10)

We combine SN constraints with BAO and CMB constraints and marginalize over the other parameters to map the likelihood of \( \Omega_\Lambda \). We find a mean value \( \Omega_\Lambda = 0.724 \pm 0.0114 \). This suggests that a universe with zero (or negative) cosmological constant is ruled out at approximately 64-σ! Amusingly, using the brute-force likelihood search that includes the positive and negative values of \( \Omega_\Lambda \), we find that the combined data give a remarkably low likelihood of zero or negative vacuum energy, even allowing for nonzero curvature: \( P(\Omega_\Lambda \leq 0) \sim 10^{-267} \). Of course, in reality, the evidence for DE is not nearly this convincing, since the likelihood in the space of cosmological observables is certainly not expected to be Gaussian this far away from the peak and thus would not be described by \( L_{\text{comb}} \propto e^{-\chi^2/2} \) (we discuss a related issue in Sec. IV). Nonetheless, it is impressive how strong the evidence for DE is with current data.

We now discuss how one goes beyond ΛCDM cosmology by parametrizing the DE equation of state.

Previous work on the effect of systematics, such as \cite{5}, considered the DE sector parametrized by its energy density relative to critical, \( \Omega_D \), and a constant equation of state \( w \). Here, we are particularly interested in extending the DE sector to allow for a time-varying equation of state. We make two alternative choices in addition to the constant equation of state so that the three parametrizations we consider are:

1. Constant equation of state, \( w = \text{constant} \);
2. Equation of state described with \( w_0 \) and \( w_a \) \cite{42}, so that \( w(a) = w_0 + w_a(1-a) \);
3. Equation of state described by a finite number of principal components of \( w(z) \) \cite{43}.

We now describe in more detail the different parametrizations of DE that we consider (constant \( w \), \( w_0 \) and \( w_a \), PCs) and then proceed to analyze the effects of SN systematics on parameter constraints.

#### B. Constant \( w \)

Assuming that DE can be described by an equation of state \( w \) that is constant in time, and assuming a flat universe, we calculate the SN-only likelihood in the \( \Omega_M-w \) plane. We marginalize over the usual nuisance parameters \( M_t, \alpha_s, \) and \( \beta_c \).

The results for SN-only constraints on \( \Omega_M \) and \( w \) are shown in Fig. I where we illustrate the effect of the systematics by showing constraints from the full covariance matrix \( C_{\text{full}} \) on top of those which assume only the diagonal statistical uncertainties \( D_{\text{stat}} \). The systematic uncertainties broaden the well-determined direction in the \( \Omega_M-w \) plane without elongating the poorly determined direction much. Constraints in either parameter are not appreciably shifted. The marginalized uncertainty for \( w \) is \( \sigma_w = 0.17 \) for diagonal errors only and \( \sigma_w = 0.20 \) when systematic errors are included. Thus systematic errors increase the uncertainty by about 20%.

We also seek to understand how SN systematics influence the stretch and color parameters \( \alpha_s \) and \( \beta_c \), not only because these correlations are what make SNe Ia useful standard candles, but also because it is expected that systematics could potentially affect these correlations. In Fig. II we marginalize over \( M_t, \Omega_M, \) and \( w \) to show constraints on the stretch and color coefficients \( \alpha_s \) and \( \beta_c \). Of particular interest is the color coefficient \( \beta_c \), which is broadly consistent with values found previously; the systematic errors shift it slightly upwards and increase errors in both parameters by a modest amount.

#### C. \( w_0 \) and \( w_a \)

We wish to understand the constraints on the redshift dependence of \( w(z) \), so we allow \( w(z) \) to have the form \cite{42,44}
\[ w(z) = w_0 + w_a \frac{z}{1+z}. \] (11)
Constraints on \( w_0 \) and \( w_a \) in a flat universe are shown in Fig. III. The shaded blue contours represent constraints.
FIG. 4. 68.3%, 95.4%, and 99.7% likelihood constraints on $\Omega_M$ and $w$, assuming a constant value for $w$ and a flat universe. We use only SN data and marginalize over the nuisance parameters. We compare the case of diagonal statistical errors only (shaded blue) with the full systematic covariance matrix (red).

FIG. 5. 68.3%, 95.4%, and 99.7% likelihood constraints on $\alpha_s$ and $\beta_c$, assuming a constant value for $w$ and a flat universe. We use only SN data and marginalize over $M$, $\Omega_M$, and $w$. We compare the case of diagonal statistical errors only (shaded blue) with the full systematic covariance matrix (red).

with only statistical SN errors assumed ($D^{\text{stat}}$), while the red contours include the full systematic SN covariance matrix ($C^{\text{full}}$). The left panel shows SN-only constraints, while the right panel shows constraints when BAO and CMB information is also included.

The figure of merit (FoM) for this model defined by the Dark Energy Task Force (DETF) \cite{55, 56} is the inverse of the area of the 95.4% confidence level region $A_{95}$ in the $w_0$-$w_a$ plane. To be precise about its normalization, we simply define the FoM as in Mortonson et al. \cite{15} as

$$\text{FoM}(w_0, w_a) \equiv (\det C)^{-1/2} \approx \frac{6.17\pi}{A_{95}}. \quad (12)$$

The approximate equality in Eq. (12) becomes exact for a Gaussian posterior distribution. The FoMs for various scenarios in the $w_0$-$w_a$ plane are given in Table III. We find that including the systematic errors reduces the FoM by about a factor of two to three.

| Scenario          | $D^{\text{stat}}$ | $C^{\text{full}}$ |
|-------------------|-------------------|-------------------|
| SN                | 2.28              | 1.16              |
| SN+BAO+CMB        | 3.28              | 11.8              |

TABLE III. Values of the DETF FoM for SN alone (middle row) and SN+BAO+CMB (bottom row). The middle column shows the FoMs for the diagonal covariance matrix $D^{\text{stat}}$ only, while the right column shows the FoMs for the full covariance matrix $C^{\text{full}}$. Note that including the systematics reduces the FoM by a factor of two to three.

### D. Principal Components

We now describe the methodology of how to calculate and constrain the principal components of DE \cite{43}, which are weights in redshift ordered by how well they are measured by a given cosmological probe and with a given survey.

Following e.g. Mortonson et al. \cite{14}, we first precompute the PCs assuming the current data centered at a fixed fiducial model (we choose the standard flat $\Lambda$CDM model with $\Omega_M = 1 - \Omega_\Lambda = 0.25$). We follow the procedure set forth by the Figure of Merit Science Working Group (FoMSWG) \cite{47} and parametrize $w(z)$ by 36 piecewise constant values in bins uniformly spaced in scale factor $a$ in the range $0.1 \leq a \leq 1.0$. We fix (i.e. ignore) all other parameters in the FoMSWG except for $\Omega_M$ and the SN Ia nuisance parameter $M$ because they are not probed by the SN Ia data, and at the same time they are effectively marginalized over in the BAO and CMB data in the distilled observable quantities, $A(z)$ and $R$ respectively, that we use. We fix curvature to zero.

3 In the Fisher matrix precomputation of the PCs we assume a single $M$ parameter as per usual practice (and following the FoMSWG parameterization), but in the actual constraints on the cosmological parameters we adopt two such parameters as described in Sec. 14A. To the extent that the PCs will be correlated anyway due to the differences between real data and assumed “data” going into the Fisher matrix, this subtle difference will be unimportant.
FIG. 6. 68.3%, 95.4%, and 99.7% likelihood constraints on $w_0$ and $w_a$ in a flat universe, marginalized over $\Omega_M$ and the nuisance parameters. The left panel shows SN-only constraints, while the right panel shows combined SN+BAO+CMB constraints. The shaded blue contours represent constraints with only statistical SN errors assumed ($D_{stat}$), while the red contours represent the full systematic SN covariance matrix ($C_{full}$). Note that the $\Lambda$CDM model $(w_0, w_a) = (-1, 0)$, represented by the black dashed lines, is fully consistent with the data.

We therefore have a $38 \times 38$ Fisher matrix (or really a $45 \times 45$ Fisher matrix with seven parameters fixed), corresponding to parameters

$$p_i \in \{w_1, \ldots, w_{36}, \Omega_M, \mathcal{M}\}.$$  

(13)

We marginalize over $\Omega_M$ and $\mathcal{M}$ and then diagonalize the remaining 36-dimensional Fisher matrix of the piecewise constant $w$ parameters. The resulting eigenvectors \( \sim \) shapes that describe $w(z)$ \( \sim \) are the PCs $e_i(z)$, and we show the 10 best-determined of these PCs, $e_1(z)-e_{10}(z)$, in Fig. 7.

The equation of state can be described as

$$1 + w(z) = \sum_{i=1}^{N} \alpha_i e_i(z),$$  

(14)

where $\alpha_i$ are amplitudes for each PC $e_i(z)$. While the Fisher matrix tells us the best accuracy to which these PCs are measured using the assumed data set (these accuracies are related to the eigenvalues $\lambda_i$ via $\sigma(\alpha_i) = \lambda_i^{-1/2}$), we are not interested in this; rather, we would like to constrain the PCs using actual current data.

We then feed the shapes in redshift of the first several PCs to the MCMC procedure to constrain these (and a few other, non-$w(z)$) parameters.

Finally, in our parameter search we impose weak priors on each $\alpha_i$, enforcing its contribution to excursions in the equation of state to the region $|1 + w(z)| \leq 1$. This approach yields top-hat priors of width

$$\Delta\alpha_i = \frac{2}{N_{z,PC}} \sum_{j=1}^{N_{z,PC}} |e_i(z_j)|$$  

(15)

centered at $w(z) = -1$ or $\alpha_i = 0$. As we will demonstrate, these priors are much wider than the allowed ranges for most of the individual PCs, meaning that our principal results are largely unaffected by the prior (Indeed, we verified this explicitly by constraining the PCs without the prior).

The pairwise constraints on all 13 parameters ($\Omega_M$, the PC amplitudes $\alpha_1 - \alpha_{10}$, and the nuisance parameters $\alpha_s$ and $\beta_c$) are shown in Fig. 8. The black curves represent constraints from the diagonal statistical SN errors only, while the red curves correspond to the full SN covariance matrix. Overall, the systematic errors broaden and shift the contours slightly.

In Fig. 9, we show the individual marginalized constraints on the 10 PC amplitudes. We are extremely encouraged by the fact that constraints on more than five of the lowest PCs are very good even with current data, a result incidentally also found by [14] using a slightly different combined “current” data set that, most notably, did not include the BOSS and WiggleZ BAO measurements. Here we again see that the SN systematics broaden the
We therefore conclude that only the lowest two PCs are affected by current systematic errors. We suspect that this is due to the fact that the effect of the systematics is smooth in redshift, and therefore systematics do not become degenerate with the higher PCs that wiggle in \( z \) (see the PC shapes in Fig. 7). It is somewhat fortuitous that higher \((n > 2)\) PCs seem to be unaffected by systematics, since it is precisely those higher PCs that are difficult to measure accurately; however, it may be the case that systematics in future data will behave differently and affect the higher components.

IV. EFFECT OF FINITE DETECTION SIGNIFICANCE OF BAO

In an interesting paper, Bassett and Afshordi [49] pointed out that for marginal detections of cosmological observable quantities, a Gaussian assumption for the likelihood may be a poor one, especially for models that are several-\( \sigma \) away from the central value of the observed quantity. This happens because the usual Gaussian likelihood implicitly ignores the possibility that the observed quantity has not actually been detected in the data at all. That possibility may have non-negligible probability, and in that case a flat likelihood in the observable may be more appropriate. In other words, writing a total likelihood of parameters \( p \) as a function of data vector \( d \), we have

\[
P(p|d) = P_{\text{detect}} P(p|d, \text{detect})
\]

\[
+ (1 - P_{\text{detect}}) P(p|d, \text{noise})
\]

where \( P_{\text{detect}} \) is the probability that the observable quantity has actually been detected and \( P(p|d, \text{detect}) \) is the likelihood of the cosmological parameters in that case. The cosmological parameter likelihood \( P(p|d, \text{noise}) \) corresponds to the case that the observable feature was actually noise, and it can be represented by a flat distribution in the parameters \( p \). Most BAO analyses effectively assume that \( P_{\text{detect}} = 1 \), thus ignoring the higher-than-expected tail in the overall likelihood coming from the nonzero second term on the right-hand side of Eq. (17).

If the BAO feature has been detected at very high significance then this is a good assumption, but it is not \textit{a priori} clear that this is the case with all of the current BAO surveys which typically have several-\( \sigma \) detection significances.

To account for the diminished power of the observations to discriminate between cosmological models when detection significance is not high, Bassett and Afshordi [49] suggest a fitting function which replaces the usual Gaussian \( \chi^2 \) expression \( \Delta \chi_G^2 \) with

\[
\Delta \chi^2 = \Delta \chi_G^2 - \frac{4 \Delta \chi_G^2}{1 + \left( \frac{S}{N} \right)^{-4} \Delta \chi_G^2},
\]

where.

![FIG. 7. The first 10 PCs, \( e_1(z) - e_{10}(z) \), used in our analysis, in order of increasing variance (bottom to top). The PCs were obtained assuming the observable quantities centered at the fiducial \( \Lambda \)CDM model, but with actual errors from the current data. See text for details.](image)
FIG. 8. 68.3%, 95.4%, and 99.7% likelihood contours for all pairwise combinations of the 13 cosmological parameters. Diagonal boxes show the 1-D marginalized likelihood for each parameter. The black contours illustrate the case of diagonal statistical SN errors only ($D^{\text{stat}}$), while the red contours include the full systematic SN covariance matrix ($C^{\text{full}}$). The parameter ordering is (top to bottom, or left to right): matter density relative to critical $\Omega_M$, the 10 PC amplitudes $\alpha_1$–$\alpha_{10}$, and the stretch and color nuisance parameters $\alpha_s$ and $\beta_c$. Note the good constraints on all parameters except for the last few PC amplitudes.

where S/N is the signal-to-noise ratio or detection significance of the observable feature or quantity. With this prescription, the quantity $\Delta \chi^2$ is equal to its Gaussian counterpart for departures from the best-fit model that are small compared to the signal-to-noise of the observed feature, but it asymptotes to a constant “tail” ($S/N)^2$ in the opposite limit, when $\Delta \chi^2_G \gg (S/N)^2$.

Here we apply this reasoning to the measurement of the BAO feature. The significances of the detection of the BAO feature are $2.4 \sigma$ (corresponding to $S/N = 2.4$).
FIG. 9. Marginalized SN+BAO+CMB constraints on the 10 PC amplitudes. The dashed vertical lines represent the prior limits. Black curves represent constraints from the diagonal statistical SN errors only, while red curves correspond to the full SN covariance matrix. Note the good constraints on all PC amplitudes except for the last few.

for 6dF [27], 2.8σ for WiggleZ [30] (combined for three redshift bins), 3.6σ for SDSS [28] (combined for two redshift bins), and 5.0σ for BOSS [32]. We expect that, once the probability of non-detection of the BAO feature has been included, the BAO constraints will change, especially for surveys with lower significance of detection and for 99.7% contour regions. This has in fact been confirmed by Bassett and Afshordi [49] for the case of the SDSS BAO data alone.

Fig. 11 shows the effects on the BAO-only (left panel) and BAO+CMB+SN (right panel) constraints in the $\Omega_M-w$ plane with and without the finite detection of the BAO features taken into account. Note that the differences are modest in the BAO-only case and negligible in the combined case. This is as expected, especially given that some of the strongest BAO data sets (e.g. BOSS) also have the highest detection significances of the BAO feature.

Note also that there is nothing BAO-specific to the effects of the finite detection significance. While the CMB is detected with very high confidence and thus does not warrant a similar analysis, it could be applied to SNe Ia where, for example, a few percent of SNe may not be Type Ia. Given the full probabilistic classification of each SN on whether or not it is Type Ia [50, 51], one could carry out a similar analysis, which in this context would be how imperfect purity of the SN Ia sample affects the constraints on cosmological parameters. We suspect the results would be even less discrepant relative to the usual perfect-detection analysis than in the case of BAO, and we do not pursue such an analysis in this paper.

In conclusion, the finite detection significance of the BAO feature in large-scale structure surveys leads to a small but discernible weakening of the constraints on cosmological parameters.

V. CONCLUSIONS

In this paper, we have investigated the effects of systematic errors in current SN Ia observations on DE parameter constraints. We accounted for the systematic errors in SN Ia observations, including the effects of photometric calibration, dust, color, gravitational lensing, and other systematics by adopting a fully off-diagonal covariance matrix between $\sim 500$ SNe from the SNLS compilation (see Fig. 2). We extended the similar analysis from Conley et al. [5] by constraining the temporal evolution of the equation of state of DE described by the pair of parameters $(w_0, w_a)$ as well as a much richer description in terms of 10 PCs of the equation of state (shown in

---

4 The results in the $w_0-w_a$ plane are qualitatively similar, and we do not show them here.

5 Conley et al. [5] find that the fraction of non-Ia SNe rises from zero at low redshift to $O(10\%)$ at $z \sim 1$; however, their modeling is very conservative, and the true fraction of non-Ia SNe is likely very small in the current data sets.
are affected by the systematics, but the overall constraints are still strong even after their inclusion (see Figs. 4 and 5). More importantly, we found that systematic errors affect the contraints somewhat, reducing the DETF FoM by a factor of about three (see Table III), while the generalized PC-based FoM is degraded by a factor of two (see Fig. 10). However, as the PC analysis shows, this degradation is mainly restricted to the first two numbers (PC amplitudes) describing DE. In fact, what is particularly impressive about current data is that more than five PCs are well-constrained even in the presence of systematic errors (see Figs. 6 and 7).

In the spirit of testing for systematic effects in current data constraining DE, we also wondered if the relatively low detection significances of BAO features ranging from about 2.4-σ to 5.0-σ in various surveys, change the overall cosmological constraints. While not a systematic error per se, a small but non-negligible probability that the BAO feature has not been detected in some of these surveys implies that the posterior probability of cosmological parameter values asymptotes to a small but nonzero value far from the likelihood peak [49]. We find that, while the BAO-only constraints are somewhat affected, the combined constraints are not (see Fig. 11).

From all this, we conclude that current systematic errors do degrade DE constraints and FoMs, but not in a major way. Given that future constraints are forecasted to be much better, continued control of current systematic errors remains key for progress in characterizing DE.
