ABSTRACT

Context. The dust properties in dwarf galaxies have been a matter of debate. High resolution data from SPITZER, HERSCHEL and PLANCK allow us to probe the entire spectral energy distribution (SED) of morphologically separated components of the dust emission from nearby galaxies and allow a more detailed comparison between data and models.

Aims. We wish to establish the physical origin of dust heating and emission based on radiation transfer models, which self-consistently connect the emission components from diffuse dust and the dust in massive star forming regions.

Methods. NGC 4214 is a nearby dwarf galaxy with a large set of ancillary data, ranging from the ultraviolet (UV) to radio, including maps from SPITZER, HERSCHEL and detections from PLANCK. We mapped this galaxy with MAMBO at 1.2 mm at the IRAM 30 m telescope. We extract separate dust emission components for the HII regions (plus their associated PDRs on pc scales) and for the diffuse dust (on kpc scales). We analyse the full UV to FIR/submm SED of the galaxy using a radiation transfer model which self-consistently treats the dust emission from diffuse dust and SF complexes components, considering the illumination of diffuse dust both by the distributed stellar populations, and by escaping light from the HII regions. While maintaining consistency with the framework of this model we additionally use a model that provides a detailed description of the dust emission from the HII regions and their surrounding PDRs on pc scales. Due to the large amount of available data and previous studies for NGC-4214 very few free parameters remained in the model fitting process.

Results. We achieve a satisfactory fit for the emission from HII+PDR regions on pc scales, with the exception of the emission at 8 µm, which is underpredicted by the model. For the diffuse emission we achieve a good fit if we assume that about 30-70% of the emission escaping the HII+PDR regions is able to leave the galaxy without passing through a diffuse ISM, which is not an unlikely scenario for a dwarf galaxy which has recently undergone a nuclear starburst. We determine a dust-to-gas mass ratio of 350-390 which is close to the expected value based on the metallicity.

Key words. dust, extinction – Galaxies: individual: NGC 4214 – Galaxies: dwarf – Galaxies: ISM – Galaxies: star formation – submillimeter: galaxies

1. Introduction

Interstellar dust is a component of the interstellar medium (ISM) that is present in all phases from dense molecular clouds to the warm ionised regions around massive stars. It plays an important role in star formation (SF) and in the overall energy budget of a galaxy. Measurements of the dust re-emission from galaxies is a powerful technique to quantify the SF. The details however, are not fully understood yet as the emission depends on several parameters as the geometry, the mixture between dust, stars and HII regions and also on the dust properties in the interstellar medium which are expected to vary as a function of metallicity and are known to depend on the environment.

The study of dust properties (e.g. mass, extinction coefficient) has been an object of debate. Much progress has been achieved in recent years due to data from the satellites SPITZER, HERSCHEL and PLANCK, which allow for the first time to probe the entire wavelength range of the spectral energy distribution (SED) of the dust emission, from the mid-infrared (MIR) to the submillimeter (submm), for a large number of galaxies at the best resolution ever.

The dust SED is a key observation for understanding the properties of dust. The dust SED of dwarf galaxies frequently shows differences to those of spiral galaxies. The main differences are: i) The SED of dwarf galaxies shows a relatively low emission at 8 µm, most likely due to a relatively lower content of polycyclic aromatic hydrocarbons (PAHs) at low metallicities (e.g. Draine et al. 2007, Galliano et al. 2008, Engelbracht et al. 2008). ii) A submm ”excess” has been found in the SED of many, mostly actively star-forming, low-metallicity galaxies (Lisenfeld et al. 2002, Galliano et al. 2003, 2005, Bendo et al. 2006, Galametz et al. 2009, 2011, Israel et al. 2010, Bot et al. 2010, Dale et al. 2012, Planck Collaboration et al. 2011a). Several reasons have been suggested to explain this excess: the existence of a large amount of cold (< 10 K) dust (Galliano et al. 2003, 2005, Galametz et al. 2009, 2011), different dust grain properties (Lisenfeld et al. 2002,Reach et al. 1995, Meny et al. 2007, ), or magnetic nanograin, which can produce magnetic dipole radiation at microwave and submillimeter wavelengths (Draine & Hensley 2012).

It is also noteworthy that one sees a variety of FIR colours for gas rich dwarf galaxies, with examples of warm FIR SEDs...
(as found from IRAS colours - e.g. Melisse & Israel 1994), or of cold FIR SEDs (as revealed by ISO and Herschel measurements extending longwands of 100 μm - e.g. Popescu et al. 2002, Grossi et al. 2010). Such variety may not be too surprising given that the star formation in dwarf galaxies is likely fundamentally bursty in nature. If we interpret the FIR SED in terms of the combination of cooler distributed cirrus dust emission and warm dust emission from grains in SF regions, the latter opaque structures should be most prominent in the early stages of the evolution of a starburst leading to a warm FIR SED. over time the starburst fades, leaving the cirrus component and a cooler FIR SED. Other factors potentially contributing to the observed variety in FIR colours are differences in the contribution of very small grains (e.g. Galliano et al. 2003, 2005) and the possible presence of extended cold dust outside the main star forming disk of the galaxy (Popescu et al. 2002).

In order to interpret the dust SED of a galaxy and to understand the differences in the SEDs of dwarf galaxies, a physical model based on realistic dust properties and taking into account the heating and emission of dust immersed in a wide range of interstellar radiation fields (ISRFs) is needed. Ideally, radiation transport in a realistic geometry should be done, but this is often difficult due to the complex geometry and large number of parameters. Models can generally be classified into three broad groups: (1) modified blackbody fits, which are too simple to describe reality correctly but give a first idea of the dust temperature ranges, (2) semi-empirical models that try, in a simplified way, to describe dust immersed in a range of different ISRFs (e.g. Dale et al. 2001, Draine et al. 2007, Galametz et al. 2009, 2011, da Cunha et al. 2008, Natale et al. 2010) and (3) models that include full radiation transfer (e.g. Popescu et al. 2011 for spiral galaxies, Siebenmorgen & Krügel 2007 for star-burst galaxies, see also Silva et al. 1998, Popescu et al. 2000, Popescu et al. 2004, Misiriotis et al. 2001, Bianchi 2008, Baes et al. 2010, 2011 and MacLachlan et al. 2011), which are the most precise description of a galaxy if all parameters, including the geometry, are known.

The new IR facilities with their high angular resolution and sensitivity allow for the first time a detailed comparison between models and data. For nearby, and thus spatially resolved, galaxies, the spatial variations of the dust SED can be probed and modelled. In particular, a good spatial resolution allows us to separate and treat the emission from dust heated by the UV radiation of massive stars in HII regions and their adjacent photodissociation regions (PDR), and the diffuse dust heated by the general ISRF.

We choose NGC 4214 as a test case because of the large amount of ancillary data and its proximity (1′′~14 pc, D=2.9 Mpc; Maíz-Apellániz et al. 2002), which allows us to observationally separate the dust emission from the two prominent central SF complexes and from the diffuse dust component in the disk. This allows us to apply a radiation transfer treatment constrained by measurements of direct light in UV to NIR and dust/PAH re-radiated light in both the diffuse and SF complexes.

We choose the radiation transfer model of Popescu et al. (2011) for spiral galaxies since this self-consistently treats the dust emission from the diffuse and SF complex components, considering the illumination of diffuse dust both by the smoothly distributed stellar populations, and by escaping light from the HII regions in spiral disks. Although NGC 4214 is a dwarf galaxy, rather than a spiral galaxy, it nevertheless exhibits the principle geometrical features of the Popescu et al. (2011) model. In particular, NGC 4214 shows an exponential disk distribution of the stellar light, the diffuse dust emission and the atomic gas emission, so is actually a good candidate to be fitted with a model for disk galaxies. While maintaining consistency with the framework of Popescu et al. (2011) model, we use the model of Groves et al. (2008) to provide a detailed description of the dust emission from the HII regions and their surrounding PDRs on scales of tens of pc. These PDRs mark the transition from the ionised medium to the dense molecular gas left over from the highly opaque cloud out of which the stars formed. The model of Groves et al. (2008) takes into account the dynamical evolution of the distance of the PDRs from the central ionising star clusters due to the mechanical effect of stellar winds on the surrounding ISM. This model is therefore particularly suitable to describe the two prominent SF complexes in the centre of NGC 4214, since these show shell structures imaged by HST surrounding the two main star clusters of the galaxy, which may be delineating wind blown bubbles around the HII regions.

NGC 4214 is a Magellanic starbursting dwarf irregular galaxy (de Vaucouleurs et al. 1991a) which shows a large degree of structure, from HI holes and shells (McIntyre 1998) typical of dwarf galaxies (Walter & Brinks 1999) to clear indications of a spiral pattern and a central bar. The molecular gas traced by the CO(1-0) line shows three well differentiated CO emitting complexes (Walter et al. 2001) related to the main SF complexes. NGC 4214 is a gas rich galaxy: the total mass of atomic gas is M_HI = 4.1 × 10^9 M_⊙ (Walter et al. 2008), and the molecular gas mass is M_CO = 5.1 × 10^9 M_⊙ (Walter et al. 2001, obtained with a Galactic conversion factor).

Karachentsev et al. (2004) reported for NGC 4214 a stellar mass of ~ 1.5 × 10^9 M_⊙, similar to the mass found in the Large Magellanic Cloud (LMC). Ultraviolet (UV), optical and near-infrared (NIR) images of NGC 4214 show that the young stellar population is embedded in a smooth disk of old stars (see the large field of Fig.1), which can account for a significant fraction (~ 75%) of the total stellar mass (Williams et al. 2011). Despite this high fraction of old stars, NGC 4214 is a galaxy with an intense recent star formation activity, as shown by the two star forming complexes located in its centre and frequently referred in the literature as NGC 4214-NW and NGC 4214-SE. When resolved, the two complexes show individual smaller knots of star formation (see the small field of Fig.1). One of the most striking features in these complexes is the large shell structure in the NW region, where most of the gas in front of the central star cluster seems to have been removed by the action of stellar winds and supernovae (SNe) (Maíz-Apellániz et al. 1998; MacKenty et al. 2000). NGC 4214-SE is more compact and shows no clear evidence of a decoupling between the star clusters and the gas. The morphological differences for the two complexes were interpreted as an evolutionary trend by MacKenty et al. (2000). Using stellar synthesis models, Ubeda et al. (2007) determined the age, the mass, the radius and the extinction of the star clusters within the NW and SE complexes. They found an age of 5 Myr for the star clusters in the NW region, whereas the age of the star clusters of the SE region ranges from 1.7 to 4.0 Myr.

The internal extinction distribution of the two complexes was studied by Maíz-Apellániz et al. (1998). These authors found that the distribution of the dust clouds is correlated with the distribution of the ionised gas: the dust is located at the border of the star clusters in the NW complex, whereas for the SE region the dust clouds seem to be co-spatial with the star clusters. The metallicities of the two complexes have been measured by Kobulnicky & Skillman (1996), who found values in the range of Z ~ 0.3 Z⊙ with little dispersion, similar to the metallicity of the Small Magellanic Cloud (SMC).
Thus, the large number and the broad range of previous studies performed for this galaxy, as well as the significant amount of multiwavelength data, give us the opportunity of obtain an accurately picture of the stellar, dust and gas components in NGC 4214.

2. The data

A wide range of data exists in archives for NGC 4214, from the UV to the submm. The entire dust emission SED from the "Mid-IR Hubble Atlas of Galaxies" (Fazio & Pahre 2004). As part of this program, NGC 4214 was observed with IRAC at 3.6, 4.5, 5.8 and 8.0 µm in May 2004. In our study of the SF regions, we only use the IRAC 3.6 µm band, which we assumed as pure stellar emission, and the IRAC 8.0 µm band. In order to isolate the dust component from the IRAC 8.0 µm we subtracted the stellar emission using the IRAC 3.6 µm image and applying the formula provided in Helou et al. (2004). With an angular resolution of 1.7′′ and 2.0′′ for the IRAC 3.6 and 8.0 µm bands, respectively, the SF complexes NW and SE are resolved into several smaller HII regions.

The total mapped area by IRAC, approximately of 13′x16′, covered the central part of the disk of NGC 4214, but not the entire extended disk. Therefore, the total emission at 3.6 and 8 µm that we obtain might be underestimated. However, judging from the IRAC 8.0 µm image in Fig. 2, we believe that the underestimate is not significant.

The uncertainty in the flux calibration is better than 10% for all IRAC (Reach et al. 2005, Fazio et al. 2004) and MIPS 24 µm bands (Engelbracht et al. 2007), and is better than 20% for MIPS 70 and 160 µm bands (Rieke et al. 2004). We adopt these numbers as the calibration uncertainties in our error estimates for the fluxes (see Sect. 3.5).

2.4. HERSCHEL

NGC 4214 was observed by HERSCHEL’s PACS and SPIRE instruments as part of the Dwarf Galaxy Survey programme (P.L. Madden), a guaranteed time key program with the aim of mapping the dust and gas in 51 nearby dwarf galaxies.

SPIRE data were obtained the 26th of June 2011 and cover a circular area of approximately 17′′. We retrieved the HIPER Level 2 images from the archive and performed further analysis for our purposes. Due to their good quality and absence of artefacts, we only subtracted the background which we measured in the same annulus used for MIPS data. The resolution of 18′′ at SPIRE 250 µm allowed us to measure individual fluxes for the two star forming complexes. This distinction was not possible in the case of SPIRE 350 and 500 µm due to a poorer image resolution (25′′ and 37′′, respectively). Swinyard et al. (2010) reported for SPIRE 250, 350 and 500 µm an uncertainty in the flux calibration of 15%, which we adopted in our error calculation.

PACS data were obtained the 27th and 28th of December 2011 and cover an area of ~25′x25′. The data from the archive were processed to level 1 with HIPER 8.2.0. To complete the reduction we used the Scanamorphos (Roussel 2012) map making technique. The background was subtracted from the final maps using the same annulus mentioned before. At the resolution of PACS at 70, 100 and 160 µm (5.2′′, 7.7′′ and 12′′, respectively), the two star forming complexes are resolved. The uncertainty in the flux calibration is of the order of 10%.

2.5. PLANCK

The “PLANCK Early Release Compact Source Catalogue” includes three detections of NGC 4214 at 350, 550 and 850 µm, all of them composed of two different observations. For the three detections the subtracted Cosmic Microwave Background (CMB) flux was less than 30% of the total flux measured originally by PLANCK. The catalogue gives two estimates for the
Fig. 1. Combined SLOAN and HST image of NGC 4214. Large field: Image of NGC 4214 from a RGB combination of SLOAN r, g and u bands. Zoom-in: Image of the centre of NGC 4214 from a RGB combination of HST-WFC3 filters F657N (H\(\alpha\) + cont), F502N ([OIII] + cont) and F336W (cont). The two circles are the apertures that we use for the aperture photometry of the regions NW and SE.

2.6. IRAM 30 m

Several observations at 1200\(\mu\)m were made by our group between December 2009 and November 2010 at the IRAM 30 m telescope on Pico Veleta (Spain), with the 37-channels bolometer array of the Max-Planck-Institut für Radioastronomie (MPIfR). The 37 pixels are located in a hexagonal structure with a beam-size of 10.8” and a pixel-to-pixel separation of about 23″. The observations were done on-the-fly and they were calibrated by observations of the planet Mars and secondary calibrators. Observations were reduced and combined into an image with Robert Zylka’s MOPSIC\(^1\) pipeline in a standard manner including baseline subtraction, spike and sky noise removal. We smoothed the combined image to a resolution of 18″ in order to increase the signal-to-noise ratio. At this resolution, the two main star forming complexes are still resolved. Our observations were not sensitive enough to detect any extended emission outside the two main SF complexes. We adopt 30% calibration uncertainty.

2.7. Thermal radio emission

The thermal radio emission in an HII region is proportional to the production rate of Lyman continuum photons \(N_{\text{Lyc}}\). Condon (1992) gives the following relation between the thermal radio emission and the extinction-corrected H\(\beta\) line flux, \(F(\text{H}\beta)\), which is proportional to \(N_{\text{Lyc}}\):

\[
S_T \sim \frac{1}{0.28} \left(\frac{T}{10^4 \text{K}}\right)^{0.52} \left(\frac{\nu}{\text{GHz}}\right)^{-0.1} F(\text{H}\beta) \times 10^{-12} \text{erg cm}^{-2} \text{s}^{-1},
\]

where \(S_T\) is the thermal flux density at the frequency \(\nu\) for an HII region with a temperature \(T\).

We use the measurements of the H\(\alpha\) emission from MacKenty et al. (2000) to calculate the expected thermal radio emission from NW and SE. They presented an H\(\alpha\) narrowband map of the centre of NGC 4214 obtained with the HST Wide Field and Planetary Camera (WFPC2). They used the spectroscopic values of the Balmer ratio H\(\alpha\)/H\(\beta\) presented by Maíz-Apellániz (2000) to correct for dust extinction and they reported intrinsic H\(\alpha\) fluxes of NW and SE. Assuming that the dust is well mixed with the gas, MacKenty et al. (2000) calculated extinction-corrected H\(\alpha\) fluxes of \(12.88 \times 10^{-12} \text{ erg cm}^{-2} \text{s}^{-1}\)

\(^1\) See http://www.iram.es/IRAMES/mainWiki/CookbookMopsic
for the NW complex and 5.75 × 10^{-12} \text{erg cm}^{-2} \text{s}^{-1} for the SE complex.

For the NW region, MacKenty et al. (2000) used a circular aperture of radius 20.6″, practically identical to the aperture used in this work (see Sect. 3.1). For the SE region they used a smaller aperture (9.96″). We therefore multiplied their flux by a factor 1.4, corresponding to the ratio of the uncorrected Hα fluxes measured from the same image in apertures of 9.96″ and 18″, respectively. Using these extinction-corrected Hα fluxes, the intrinsic Hα/Hβ ratio and the temperature of 10^4 K reported by Kobulnicky & Skillman (1996), we obtain with Eq. 1 flux densities at 8.46 GHz (3.5 cm) of 13 and 8 mJy for NW and SE, respectively.

The combined prediction for the thermal radio emission of NW and SE (21 mJy) can be roughly compared with the measurement from the VLA at 8.46 GHz of 24.2±4.8 mJy given by Kepley et al. (2011) for the total radio emission, which includes synchrotron and thermal emission. From the uncorrected Hα emission, Kepley et al. (2011) estimated that the fraction of thermal emission is on average ~ 0.5 (see Fig. 9 in their paper). However, since these authors did not correct the Hα emission for dust attenuation, their estimation gives a lower limit of the thermal fraction. Our estimation of free-free emission (21 mJy) falls within the limits of thermal fractions of 0.5 (12.1 mJy) and 1.0 (24.2 mJy) and is thus consistent with their data. We used their limits to roughly estimate an error of the thermal radio flux of ~ 30%.

3. Photometry

We need to separate the dust emission from the two major SF complexes NW and SE and the diffuse disk, in order to establish the individual SEDs of these morphological components. We therefore independently carried out aperture photometry for the regions SE and NW and for the total emission of the entire galaxy. We determined the diffuse dust emission as the difference between the total emission and the sum of the emissions of SE and NW regions.

Prior to extracting the photometry, we regridded all the images to a common pixel size keeping the original resolution of each image. Then, corresponding aperture corrections were applied to the fluxes in each band. In this section we describe how we performed the aperture photometry, which corrections were applied and how the errors were handled.

3.1. Apertures

We chose the apertures around the HII regions large enough to enclose the entire localized dust emission and simultaneously tried to include as little as possible emission from the diffuse component. Mainly based on the MIPS 24 μm image, we chose apertures with radii of 21″ and 18″ for the NW and SE complexes (see Figures 1 and 2), respectively. The 24 μm image was used as it is the filter which is expected to most faithfully trace the warm dust in thermal equilibrium with the strong radiation fields from the star clusters in the PDRs and HII regions associated with the SF regions. We were able to measure the emission from each SF complex only for those wavelengths where both complexes were spatially resolved, which excluded the maps of MIPS 70 and 160 μm and SPIRE 350 and 500 μm. The measured, background-subtracted fluxes are listed in column 3 in Tables 1 and 2 for NW (F_{NW}^{\text{sub}}) and SE (F_{SE}^{\text{sub}}), respectively.

One issue of particular relevance to the quantitative analysis presented in this paper is that of the subtraction of the local background underlying the NW and SE SF regions. Ideally, we need to cleanly separate the localised dust/PAH emission associated with the HII regions and the local PDRs on scales of tens of parsecs (marking the interface between the tenuous gas ionised by the star cluster and the dense material of the parent molecular clouds) from the underlying extended emission from diffuse dust distributed on the kpc scale of the disk. In practice it is very challenging to perform such a separation, not only because of blending effects due to the finite angular resolution (these are quantified through the aperture corrections described in Sect. 3.2, below) but also because of the limited range of UV photons which have escaped the SF regions and have passed into the diffuse dust layer, forming a halo around the SF regions.

The extent and brightness of this diffuse halo emission is expected to vary strongly with infrared wavelength in a way which is both difficult to measure directly and also uncertain to predict theoretically on an a priori basis. Therefore, for simplicity, we have opted in this paper to make no attempt to subtract the underlying diffuse background when performing aperture photometry on the SE regions. For future reference we simply note here that we may thereby be overestimating the flux densities of the NW and SE SF regions, most particularly in the PAH bands, but also to some extent around the peak of the SED in the FIR. The effect at 24 μm, however, is likely to be small, since, as already noted, this band is primarily sensitive to warm dust heated by the intense radiation fields in the PDRs and HII regions close to the star clusters.

For the measurement of the total emission of NGC 4214 we chose an aperture of 5″ in radius (see Figure 2). We tested with growth curves at all wavelengths that this aperture enclosed the entire emission of the galaxy. For the PLANCK measurements, which include the total emission of the galaxy, the apertures could not be chosen. However, their values are very close (see Section 2.5) to ours, and our growth curves showed that at the radius of the PLANCK beam the emission was enclosed completely.

The total emission from the MAMBO 1.2 mm map is more uncertain due to the poor signal-to-noise ratio at the outer parts of the area covered by our observations, which is practically the same as the aperture of 5″ used for the other images. In the moderately smoothed image (resolution 18″, shown in Fig. 2) no diffuse emission can be seen. However, when we smooth the map to an angular resolution of 40″ diffuse dust emission becomes visible in the inner 160″ whose structure corresponds very well to the SPIRE 500 μm map. Beyond this radius we are not sure that the structures are real. The growth curve of MAMBO keeps rising until ~ 200″ where it becomes approximately flat. We obtained integrated fluxes of 0.26±0.03 Jy and 0.35±0.11 Jy for the apertures of 160″ and 300″, respectively. The lower value should represent a reliable lower limit for the total flux in NGC 4214.

The total flux is more uncertain, however, given the flatness of the growth-curve beyond 200″, we are therefore confident that the flux at 300″ is a reasonable estimate. Due to these uncertainties, we did not include the MAMBO data point in our fitting procedure but we show it in the figures for comparison with the models.

The measured, background-subtracted fluxes of the total emission are listed in column 3 of Table 3.

3.2. Aperture correction

Because of the different resolutions of the images we applied aperture corrections to the NW and SE IR fluxes. We derived values of the aperture correction by adopting the IRAC 8μm as
Fig. 2. Images of NGC 4214 at different wavelengths. The large circle shows the aperture that we chose for the entire disk emission and the smaller circles in the top-left panel the aperture to measure the emission from the HII regions NW and SE.
Table 1. Flux densities for region NW obtained for an aperture of 21″ radius centred at RA=12h15m39.6s Dec=+36°19′36.5″ (J2000) (see Figs 1 and 2). $F_{\text{NW}}^{\text{sub}}$ is the measured, background-subtracted flux and $F_{\text{NW}}$ is the final flux, after applying aperture and colour corrections. (**) The contribution from thermal radio emission was not subtracted.

Table 3. Flux densities of NGC 4214 for an aperture of 5′ radius centred at RA=12h15m39.1s Dec=+36°19′34.5″ (J2000) (see Fig. 2). $F_{\text{DISK}}$ is the measured, background-subtracted flux, $F_{\text{DISK}}$ is the final flux of the entire galaxy, after applying colour correction, and $F_{\text{DIFF}}$ is the flux of the diffuse emission obtained as $F_{\text{DISK}} - (F_{\text{NW}} + F_{\text{SE}})$. The lower error of $F_{\text{DIFF}}$ includes the contribution of smaller and less intense SF regions in the disk (see Sect. 6). (**) The contribution from thermal radio emission was not subtracted.
the high-resolution model of the flux distribution. We first measured the flux within the NW and SE apertures in the IRAC 8 µm image. Then we convolved the IRAC 8 µm image with the point-spread-function (PSF) of MIPS 24, PACS 70, PACS 100, PACS 160, SPIRE 250 and MAMBO, and measured again the flux within the same apertures. The ratio between the flux measured in the original and convolved images gives the aperture correction for each band. The values are listed in column 4 of Tables 1 and 2.

3.3. Colour corrections

In order to directly compare the monochromatic fluxes with the models of Popescu et al. (2011) and Groves et al. (2008), we applied colour corrections to the IRAC, MIPS, PACS, SPIRE and PLANCK fluxes. We followed the procedures described in the corresponding manuals2, where colour correction factors for different source distributions are listed.

We chose the colour correction factors for the spectrum that most closely resembled the model spectrum at a given wavelength. For the MIPS 24 µm band we adopted a blackbody with a temperature of 70 K, for the MIPS 70 µm, MIPS 160 µm and PACS bands a blackbody with temperature of 50 K, for SPIRE bands and PLANCK 350 µm we chose a power-law spectrum with \( \alpha = +2.0 \), for PLANCK 550 µm a power-law spectrum with \( \alpha = +2.5 \), and for PLANCK 850 µm a power-law spectrum with \( \alpha = +3.0 \) (where the exponent \( \alpha \) is defined as \( F_\nu \propto \nu^\alpha \)). For the particular case of IRAC 8 µm, we adopted the colour correction for a PACA-dominated spectrum. At 8 µm we additionally compared model and data by generating synthetic integrated fluxes. For this we (i) multiplied the model spectrum with the 8 µm filter profile and integrated it over the 8 µm filter band and (ii) multiplied the observed 8 µm data, adopting the blackbody of \( T = 10^4 \) K profile on which the flux definition of IRAC is based, with the 8 µm profile and integrated it over the 8 µm filter band. The comparison of both values allowed an alternative estimate of the goodness of the fit, based entirely on the data and the model spectrum. We found that this comparison produced within 10% the same ratios as the comparison between colour corrected data point and model flux.

The colour corrections are listed in Tables 1, 2 and 3.

3.4. Line contamination

Most of the FIR/submm broad-band filters used for this work are contaminated by molecular or atomic emission lines. In the cases where data were available, we estimated the line contamination by comparing the luminosity of the emission line with the total luminosity measured in the filter, obtained by integrating the product of the source spectrum and the spectral response of the filter over the frequency range of the filter band.

Emission lines from different CO rotational transitions fall into SPIRE, PLANCK and MAMBO filters. We used the CO(1-0) map presented by Walter et al. (2001) as a reference. We determined a velocity integrated flux of 9.3 Jy km s\(^{-1}\) in the NW region and 12.8 Jy km s\(^{-1}\) in the SE region. The MAMBO filter band, with a bandwidth of about 80 GHz, is affected by the CO(2-1) line. We estimate the flux of the CO(2-1) line from the measured CO(1-0) value assuming that the line intensity ratio it is given by the value for optically thick, thermalised CO, \( I_{\text{CO}(1-0)}/I_{\text{CO}(2-1)} = 1 \). The contribution of the CO(2-1) line to the total measured flux at 1.2 mm of the NW and SE complex is then 0.87% and 1.27%, respectively. For other bands, the contamination by higher CO transitions is more than an order of magnitude smaller.

PACS spectroscopic maps of atomic FIR lines ([OI] 63, [OIII] 88, [NII] 122, [OI] 146, [CII] 158 and [NII] 205 µm) of NGC 4214 were presented by Cormier et al. (2010). With a field of view of 1.6 x 1.6, only the central part of the galaxy is observed. However, this region completely covers the main SF complexes NW and SE where the major part of the line emission originates. Therefore, we do not expect to severely underestimate the total emission of these lines. [OI] 63 and [OIII] 88 µm fall into the bandpass of the MIPS 70 and PACS 70 filter. The luminosities reported by Cormier et al. (2010) are 0.89 x 10\(^6\) \( L_\odot \) for [OI] 63 µm and 1.99 x 10\(^6\) \( L_\odot \) for [OIII] 88 µm. The sum of these values corresponds to 1.11% (1.33%) of the total luminosity measured in the PACS 70 (MIPS 70) band. [OIII] 88 µm fall into the bandpass of the PACS 100 filter. Its luminosity corresponds to 1.73% of the total luminosity measured in the PACS 100 band. [OI] 146 and [CII] 158 µm fall into the bandpass of the MIPS 160 and PACS 160 filter. The reported luminosities for [OI] 146 and [CII] µm lines are 0.05x10\(^6\) \( L_\odot \) and 2x10\(^6\) \( L_\odot \), respectively, which together represents 2.88% (4.26%) of the total luminosity measured in the PACS 160 (MIPS 160) band.

Due to the small contribution from the atomic and molecular lines to the FIR/submm bands, we did not apply any decontamination to our measurements except for the PACS 160 and MIPS 160 bands. These have been included in Tables 1, 2 and 3.

3.5. Error handling

In our error analysis we took into account three types of error: (i) calibration, \( \Delta_{\text{cal}} \), for which we adopted the values mentioned in Sect. 2, (ii) measurement error due to background fluctuations, \( \Delta_{\text{back}} \), and (iii) an estimate of the error due to the uncertainty in the aperture size of regions NW and SE, \( \Delta_{\text{apert}} \) (this error was not relevant for the total emission). We neglected the uncertainties introduced by the colour and aperture corrections.

The error due to the background fluctuations was calculated assuming that each pixel within the aperture has an error given by the standard deviation of the background noise, \( \sigma_{\text{back}} \). In addition, we had to take into account the error of the background which was subtracted within an aperture of \( N_{\text{apert}} \) pixels. This error is \( \sigma_{\text{back}} N_{\text{aper}} \sqrt{N_{\text{back}}} \), where \( N_{\text{back}} \) is the number of pixels used to compute the level of background. This gives (see also Dale et al. 2012) a total error for the background subtracted flux of:

\[
\Delta_{\text{back}} = \sigma_{\text{back}} \sqrt{
\frac{N_{\text{aper}}^2}{N_{\text{back}} \sigma_{\text{back}}} + 1}
\]

We estimated the error \( \Delta_{\text{apert}} \) by changing the aperture size for the regions NW and SE by ±1°. We obtained changes in the integrated fluxes between 4 and 8% for the different bands. We adopted conservatively an error of \( \Delta_{\text{apert}} = 8\% \) for all bands.

The final error for the flux is the quadratic sum of \( \Delta_{\text{cal}}, \Delta_{\text{back}}, \) and \( \Delta_{\text{apert}} \). This is listed in Tables 1, 2 and 3 for the fluxes in each band. The dominant error sources were \( \Delta_{\text{cal}} \) and \( \Delta_{\text{apert}} \), whereas \( \Delta_{\text{back}} \) was found to be negligible for most wavelengths.

4. Models for the dust emission

We analyse the full UV to FIR/submm SED of the different emission components of the galaxy using the radiation transfer model of Popescu et al. (2011), which self-consistently treats the dust emission from diffuse and SF complexes components, considering the illumination of diffuse dust both by the distributed stellar populations, and by escaping light from the HII regions. While maintaining consistency with the framework of Popescu et al. (2011) model, we use the model of Groves et al. (2008) to provide a detailed description of the dust emission from the two central SF complexes NW and SE. In the following sections we present a brief description of the physics and parameters of these models.

4.1. The model of Popescu et al. (2011)

Popescu et al. (2011) presented a self-consistent model based on full radiative transfer calculations of the propagation of starlight in disk galaxies. To approximate the large scale geometry of the galaxy (see Fig. 1 in Popescu et al. 2011), they used two separate components: (i) an old component consisting of an old stellar disk, an old stellar bulge and a dust disk, and (ii) a young component consisting of a young stellar disk and a dust disk. The young component is introduced to mimic the more complex distribution of young stars and diffuse dust associated with the spiral arms. Apart from the diffuse component, the model includes a clumpy component, consisting of the parent molecular clouds of massive stars. The input parameters of this model are:

- The total central face-on B-band opacity, \( \tau_0 \), which is the sum of the central face-on B-band opacities of the young and old dust disks.
- The star formation rate, \( SFR \).
- The clumpiness factor \( F \), which can be physically identified with the luminosity-weighted mean fraction of directions from the massive stars, averaged over the lifetime of the stars, which intersects the birth-cloud. The clumpiness factor \( F \) is linked to the fraction of photons that escapes \( f_{esc} \) from the SF regions into the diffuse medium as \( F = 1 - f_{esc} \).
- The normalized luminosity of the old stellar disk, \( old \).
- The bulge-to-disk ratio, \( B/D \), which determines the bulge contribution to the old stellar radiation field.
- The radial scale-length of the old stellar disk, \( h_s \), which defines the size of the galaxy. All other spatial scales in the galaxy (scale-length of the young stellar population, scale-length of the dust and vertical scale-heights for the different components) have a constant ratio with \( h_s \) (see Table E.1 in Popescu et al. 2011).
- The inclination angle, \( i \).

From the primary parameters \( SFR \) and \( F \), Popescu et al. (2011) define the star formation rate powering the diffuse emission, \( SFR' \), as it follows (Eq. 45 in Popescu et al. 2011):

\[
SFR' = SFR \times (1 - F)
\]  

(3)

The library of diffuse SEDs of Popescu et al. (2011) contains results for a four-dimensional parameter space spanned by \( \tau_0, SFR', old \) and \( B/D \). The diffuse component is calculated as an extrinsic quantity corresponding to a reference size (corresponding to a reference scale-length). In order to scale the intensity of the ISRF heating the diffuse dust in a galaxy, the parameters \( SFR' \) and \( old \) must be scaled to the reference size by comparing the scale-lengths (Eq. D.3 in Popescu et al. 2011):

\[
SFR_{model} = SFR' \times \left( \frac{h_s}{h_s(B)} \right)^2
\]  

(4)

\[
old_{model} = old \times \left( \frac{h_s}{h_s(B)} \right)^2
\]  

(5)

where \( h_s(B) = 5670 \text{ pc} \) and \( h_s(B) \) are the reference B-band scale-length and the B-band scale-length of the galaxy under study, respectively. We note here that \( SFR_{model} \) and \( old_{model} \) are only internal parameters that allow us to interface with the library of models. Because of this all the results in this paper are presented only in terms of the \( SFR \) and \( old \), the real parameters of the galaxy under study.

An additional scaling is required to set the flux levels of the SEDs from the library to the observed SED of our galaxy. Thus, the SED that represents our galaxy, \( F_\lambda \), is determined as (Eq. D.2 in Popescu et al. 2011):

\[
F_\lambda = \left( \frac{h_s(B)}{h_s(B)} \right)^2 \times F_{\lambda, model}(\frac{B}{D}, \tau_s, SFR_{model}, old_{model}).
\]  

(6)

We would like to stress that in these models the absolute flux level of the predicted dust SED is fixed by the input parameters.

The models of Popescu et al. (2011) have been designed to provide the formalism for fitting the integrated emission of galaxies, since for most galaxies resolved information on the dust emission is not available. In particular dust emission SEDs of individual star-forming complexes cannot be derived in most cases. Consequently, the model of Popescu et al. (2011) provides an average template SED for the dust emission of the ensemble of the HII regions. This template has been empirically calibrated on data of a representative sample of prominent star forming complexes in our Galaxy, as fitted using the model of Groves et al. (2008). By contrast, in this study of NGC 4214, we have resolved information on the central star forming complexes, and can therefore replace the average template with a detailed modeling of these complexes using directly the model of Groves et al. (2008), while still retaining the general framework of the model of Popescu et al. (2011), when calculating the attenuation of stellar light in the clumpy component. This allows us to reach a self-consistent treatment of the diffuse and clumpy component, mediated by the fact that the two models used here have a common parameter, the \( F \) factor.

4.2. The model of Groves et al. (2008)

The model of Groves et al. (2008) describes the luminosity evolution of a star cluster of mass \( M_\star \), and incorporates the expansion of the HII region and PDR due to the mechanical energy input of stars and SNe. The dust emission from the HII region and the surrounding PDR is calculated from radiation transfer. The main input parameters of the model are:

- The metallicity of the star cluster, \( Z \), in units of the solar metallicity \( Z_\odot \) (Asplund et al. 2005). The metallicities used in the model are restricted to the SMC and LMC metallicities. This limitation is introduced by the stellar population model (Smith et al. 2002).
- The age of the star cluster, \( t \).
– The ambient pressure, $\log(p_0/k)$, which controls the rate of the expansion of the HII region and PDR due to the mechanical energy input of stars and SNe, and the size. Therefore $\log(p_0/k)$ determines the dust temperature for a given star cluster mass and age.
– The compactness parameter, $\log(C)$, which parametrizes the heating capacity of the star cluster and depends on $M_{cl}$ and $\log(p_0/k)$.
– The covering factor, $f_{cov}$, which represents the fraction of the surface of the HII region covered by the PDR. This is the same parameter as the $F$ factor in the model of Popescu et al. (2011).
– The hydrogen column density of the PDR, $N_{HI}^{PDR}$.

At a given age, the model self-consistently calculates the luminosity distribution of the star cluster and the radius of the inner edge of the PDR and computes the emergent SED for the dust in the HII region without considering the PDR, $F_{\lambda}^{HII}$, and for the dust from the HII region which is completely covered by a PDR, $F_{\lambda}^{HII+PDR}$. The total emergent SED from the star forming region which is partially covered by the PDR, $F_{\lambda}^{SF}$, is then given by:

$$F_{\lambda}^{SF} = (1 - f_{cov}) \times F_{\lambda}^{HII} + f_{cov} \times F_{\lambda}^{HII+PDR}$$

5. Constraints on the input parameters

The large amount of ancillary data covering a wide wavelength range, as well as the result of previous studies from the literature allow us to determine or at least constrain most of the input parameters for both models.

5.1. Input parameters for the model of Groves et al. 2008

The two main SF complexes NW and SE are formed by an ensemble of smaller HII regions. Ideally, all these smaller knots of SF should be modelled separately. However, IR/submm observations lack the angular resolution to perform such a detailed analysis. Due to this limitation, for both complexes we adopt parameter ranges which are wide enough to enclose the values of their individual knots. With the only exception of $N_{HI}^{PDR}$, for which we adopted the value $10^{22}$ cm$^{-2}$, typical of molecular clouds in our own galaxy, the input parameters of the model of Groves et al. (2008) were observationally constrained:

(i) Metallicity: The metallicities of both SF regions have been measured by Kobulnicky & Skillman (1996), who found values of $12 + \log(O/H) = 8.17 \pm 0.02$ for the NW and $8.27 \pm 0.02$ for the SE region. With the Solar abundance $12 + \log(O/H) = 8.66$ (Asplund et al. 2005), as used in Groves et al. (2008), this gives $Z = 0.32 Z_{\odot}$ for NW and $Z = 0.41 Z_{\odot}$ for SE. We used a metallicity of $Z = 0.4 Z_{\odot}$ and also tested $Z = 0.2 Z_{\odot}$, which yielded a similar result (no template for $Z = 0.3 Z_{\odot}$ is available in Groves et al. 2008).

(ii) Age: The age of the star clusters of NGC 4214 have been extensively studied by different authors. Leitherer et al. (1996) presented HST Faint Object Spectrograph (FOS) ultraviolet spectra covering the main star cluster of the NW complex. Using spectral synthesis modelling, Leitherer et al. (1996) reported for this stellar cluster an age of 4-5 Myr. Maíz-Apellániz et al. (1998) obtained optical long-slit spectra of NGC 4214 with the ISIS spectrograph of the William Herschel Telescope. Their bidimensional spectra covered both SF complexes. From the comparison of different observationally determined parameters (equivalent width of H$\beta$, Wolf-Rayet population, effective temperature and UV absorption lines) to synthesis models, they determined ages of $3 \pm 1$ Myr for both regions. MacKenty et al. (2000) mapped the central part of NGC 4214 with the HST Wide Field Planetary Camera 2 (WFPC2). From the $H_\alpha$ equivalent width, these authors determined an average age of 3.0-4.0 Myr and 2.5-3.0 Myr for the NW and SE regions, respectively. More recently, Ubeda et al. (2007) also used the WFPC2 data set to determine the ages of the star clusters by a likelihood-maximization technique from the photometric colours. They determined an age of 5 Myr and of 2-4 Myr for the star clusters within the NW and the SE complex, respectively. Based on the dispersion found by these studies, we adopted ages of the NW and SE complexes of 3-5 Myr and 2-4 Myr, respectively.

(iii) Ambient pressure and Compactness: $\log(p_0/k)$ and $\log(C)$ were determined by comparing the expected and the observed radii of the individual HII regions as a function of the age. For a cluster of a given age it is possible to find different combinations of $\log(p_0/k)$ and $\log(C)$ that provide the observed radius of the expansion bubble. However, this degeneracy can be avoided when the mass of the star cluster is known, since both parameters $\log(p_0/k)$ and $\log(C)$ are related by the equation:

$$\log \left( \frac{M_{cl}}{M_{\odot}} \right) = \frac{5}{3} \times \log(C) - \frac{2}{3} \times \log \left( \frac{p_0/k}{\text{cm}^{-2}\text{K}} \right)$$

From the values of the masses reported by Ubeda et al. (2007) we obtained that for the NW complex the value of $\log(p_0/k)$ ranges from 7.0 to 8.0 and $\log(C)$ ranges from 5.5 to 6.5 depending on the HII region considered. For the case of the SE complex, we found that $\log(p_0/k)$ ranges from 6.0 to 7.0 and that $\log(C)$ ranges from 4.5 to 5.5. We used these intervals to constrain both parameters.

(iv) Covering factor: We assumed that the PDR consists of optically thick, homogeneously distributed clouds that surround the star cluster, leaving a fraction unattenuated so that the light can escape unattenuated from these "holes". To a good approximation, the intrinsic luminosity of the central star cluster is the sum of the observed luminosities of the stars, $L_{\text{star}}$, and the luminosity re-emitted by the dust, $L_{\text{dust}}$. The covering factor is then $f_{cov} = L_{\text{dust}}/(L_{\text{dust}} + L_{\text{star}})$. We obtained $L_{\text{dust}}$ by integrating the best-fit model template (see Sect. 6) from 3$\mu$m to 1.5 mm. To calculate $L_{\text{star}}$ we integrated the de-attenuated fluxes measured in our apertures for the SF regions from GALEX FUV to IRAC 3$\mu$m. The exact value of the opacity in front of the SF regions due to the diffuse dust layer is not known. For this reason, we carried out two different estimates, the first based on the lowest and the second on the highest realistic opacity. i) We adopted the foreground opacity of $\tau_{\gamma} = 0.35$ (Ubeda et al. 2007) measured locally in front of the main stellar cluster of the NW region and assumed that this value is representative for both SF regions. The stars in the NW region seem to have evacuated most of the surrounding material associated with the HII region so that this value is expected to be lower than the average disk opacity in this area. We obtained $f_{cov}^{nw} = 0.45$ and $f_{cov}^{se} = 0.65$ for the NW and SE regions, respectively. ii) We used the value of $\tau_{\gamma} = 0.7$ which is the best fit value derived from our modelling of the diffuse emission (see Sect. 6). Assuming that the regions are in mid-plane and using the inclination angle $i = 44^\circ$ (Walter et al. 2008), the opacity in front of the SF complexes is calculated as $0.5 \times \tau_{\gamma}/\cos(i) = 1.4$. In this case, we obtained $f_{cov}^{nw} = 0.20$ and $f_{cov}^{se} = 0.30$. Thus, we obtain estimates for the covering factor of $f_{cov}^{nw} = 0.20 - 0.45$ and $f_{cov}^{se} = 0.30 - 0.65$ for both regions.
In the case of the model of Popescu et al. (2011) the parameters that we used were the mean value from the upper and the lower limits for both regions. With the exception of the log($p_{\text{cov}}$) for both regions, the best-fit model value (see below) was taken. The values for the diffuse dust emission are listed in Table 3. In order to take into account the emission from smaller and less intense SF regions in the disk of NGC 4214, we estimated their contribution from the Hα emission of the ten brightest secondary SF regions which corresponds to 18% of the Hα emission of SE+NW. We assume that the shape of the dust SED from these smaller SF regions is the same as the sum of the SEDs of SE+NW, and we include their contribution in the calculation of the lower error range of the fluxes of the diffuse dust component in each band (see Table 3). The smaller HII regions only have a noticeable effect on the emission at 24 μm and 70 μm.

6. Results

In a first step we separately fitted the emission from the SF regions and from diffuse dust. In a second step we self-consistently combined the emission from the SF regions with that from the diffuse dust to fit the total emission of the galaxy.

The emission from the NW and SE regions have been directly measured from the maps as described in Section 3. The diffuse emission has been calculated as the difference between the total emission and the sum of the emission from the two SF complexes. For the data points where no direct measurement was available, the best-fit model value (see below) was taken. The values for the diffuse dust emission are listed in Table 3.

### 6.1. Best fits for the SF regions

The best-fit models for the NW and SE complexes are shown in Figures 4 and 5, respectively.

We obtained a good fit for all our observed photometric points longwards of 10 μm. For a metallicity of $Z = 0.4 Z_\odot$, the best-fit models of the two complexes correspond to the parameters $t = 4.0 \text{ Myr}$, $\log(C) = 5.0$, $\log(p_{\text{cov}} / k) = 8$ and $f_{\text{cov}} = 0.30$ for both regions. With the exception of the log($C$) of the NW region and log($p_{\text{cov}} / k$) of the SE region, all the parameters fall within our parameter ranges constrained from the observations.
Fig. 4. Best-fit models to the NW complex for $Z = 0.4 \ Z_\odot$ (solid line) and $Z = 0.2 \ Z_\odot$ (dashed line). The values of the reduced $\chi^2$ (neglecting the IRAC 8 $\mu$m point) are 0.25 and 0.75 for $Z = 0.4$ and $0.2 \ Z_\odot$, respectively.

Fig. 5. Best-fit model to the SE complex for $Z = 0.4 \ Z_\odot$ (solid line) and $Z = 0.2 \ Z_\odot$ (dashed line). The values of the reduced $\chi^2$ (neglecting the IRAC 8 $\mu$m point) are 1.17 and 0.89 for $Z = 0.4$ and $0.2 \ Z_\odot$, respectively.
(see Sect. 5.1). For a metallicity of Z=0.2 Z⊙ the best fit parameters are in the case of the NW region $t=5.0$ Myr, $\log(C)=5.0$, $\log(p_0/k)=7$ and $f_{\text{cov}}=0.30$ and in the case of the SE region $t=3.5$ Myr, $\log(C)=4.5$, $\log(p_0/k)=8$ and $f_{\text{cov}}=0.60$. The value for $\log(C)$ in NW is slightly lower, and $\log(p_0/k)$ in SE slightly higher, but the rest of the parameters are within the observed ranges.

We note that the IRAC 8 μm data point was excluded from our fitting procedure. The reason is that both models considerably underestimate the emission at 8 μm. Specifically, from our best-fit models for Z=0.2 Z⊙ we obtained that the observed fluxes are larger than the model values by a factor of 3.8 and 4.0 for NW and SE, respectively. In the case of the best-fit models of Z=0.4 Z⊙ the discrepancy decreases to a factor of 3.1 and 2.9 for NW and SE, respectively. A complete discussion of the IRAC 8 μm discrepancy will be given in Sect. 7.

### 6.2. Best fit for the diffuse emission

We searched the library of the diffuse dust SEDs of Popescu et al. (2011) for the best fit to the data in the MIR/submm range, leaving $\tau_8$ and $SFR'$ as free parameters and keeping old fixed to the value 0.009. Fig. 6 shows the best fit obtained for our measured value $h_8=873$ pc (solid red line), where we determined as best-fit values $\tau_8=2$ and $SFR'=0.059 M⊙\text{yr}^{-1}$. Neither the data point at 8 μm micron nor at 12 μm were taken into account in the $\chi^2$ fitting procedure, the latter due to the observational limitations discussed in Sect. 3.1.

The model fits the data points in general very well. The largest discrepancy occurs at 8 μm where the model overpredicts the observations by a factor of 1.9. We will discuss this further in Sect. 7. At 160 μm there is a discrepancy with the PACS value which is overpredicted by 34% by the model, but the model prediction agrees within the errors with the MIPS data point at the same wavelength. The model overpredicts the SPIRE 250 μm point by 24% and underpredicts the 850 μm point by 34%. For the other data points the model predictions agree within the error bars.

It is instructive to compare this value of $SFR'$ derived from the fit to the diffuse component of the dust emission, with the value for $SFR'$ derived from our measurement of the spatially integrated flux density in the UV-to-blue band and which we will call, for clarity, $SFR'$ UV in the following. Applying the attenuation corrections due to diffuse dust, as tabulated in Popescu et al. (2011) for $\tau_B=2$ and an inclination of 44° we derive a value of $L_{UV}=3.70 \times 10^{35}$ W. We then determine $SFR'$ UV following Eq. 17 in Popescu et al. (2011) as $SFR'_{UV}=L_{UV}/L_{\text{att,UV}}$, where $L_{\text{att,UV}}$ is the normalization factor. We obtain $SFR'_{UV}=0.165 M⊙\text{yr}^{-1}$. This is a factor of 2.8 times higher than the value of $SFR'$ derived from the fitting of the diffuse dust emission. The most straightforward explanation for this discrepancy would be that the true value for the disk scale length $h_8$ is higher than the adopted of 873 pc. This would favour a disk with lower dust surface densities, leading to a higher value of $SFR'$ needed to account for the observed amplitude and colour of the diffuse dust emission. If we adopt for the scale-length the maximum allowed by the B-band images, $h_8=1045$ pc, we obtain a best fit to the diffuse dust emission SED of $\tau_B=1.2$ and $SFR'=0.088 M⊙\text{yr}^{-1}$. At the same time, this reduction in $\tau_B$ means that the deattenuated, integrated UV luminosity, $L_{UV}$, is now lower, yielding $SFR'_{UV}=0.147 M⊙\text{yr}^{-1}$ which is only a factor of 1.67 greater than the value of $SFR'$ derived from the diffuse dust emission. A complete discussion of this discrepancy will be given in Sect. 7.

As a further consistency check we can use the value of $SFR'$ derived from the diffuse dust emission to make a different, global estimate of the fraction of the UV radiation escaping from the SF regions, $f_{\text{esc}}$, and the corresponding clumpiness factor, $F$, and compare it with the corresponding value already derived in Sect. 5 from analysis of the direct and dust-re-radiated UV light seen from the spatially resolved SF regions. For this, we have to assume that the effective star formation rate powering the diffuse dust, $SFR'$, is due to radiation escaping from the regions NW and SE. The total effective SFR produced by NW+SE is then $SFR'+SFR'_{loc}$ where $SFR'_{loc}$ is the effective star-formation rate needed to power the dust emission from the SF regions. We calculate $SFR'_{loc}$ by integrating the dust SED from the SF regions over the entire wavelength range, obtaining $L_{\text{dust}}$, and assuming that this luminosity is equivalent to the same amount of UV radiation absorbed by the dust locally. We then determine $SFR'_{loc}$ in an equivalent way as described for $SFR'_{UV}$ above, as $SFR'_{loc}=L_{\text{dust}}/L_{\text{att,UV}}$. We obtain $L_{\text{dust}}=9.06 \times 10^{34}$ W, which gives $SFR'_{loc}=0.040 M⊙\text{yr}^{-1}$. With $SFR'=0.059 M⊙\text{yr}^{-1}$, derived from our best fit for the diffuse emission, we then obtain $f_{\text{esc}}=SFR'/(SFR'+SFR'_{loc})=60$% of the UV radiation of the SF region is required to escape from the SF complexes in order to heat the diffuse dust. This escape fraction corresponds to a $f_{\text{esc}}=F=1-0.60=0.40$, which is the same value derived in Sect. 5. We thus adopt in the following $F=0.40 \pm 0.20$ (where the error comes from the range of $f_{\text{esc}}$ derived in Sect. 5.1).

From the best-fit value of $SFR'$ and $F=0.40$ we can estimate the value of the total star formation rate of NGC 4214 as $SFR=SFR'/(1-F)=0.059/(1-0.40)=0.098 M⊙\text{yr}^{-1}$.

### 6.3. Best fit for the total emission

On the MIR/FIR/submm part of Fig. 7 we show the fit to the total dust emission, which is the sum of the SEDs from the SF regions and the SED from the diffuse dust obtained in the previous sections. The entire dust SED from 8 μm to 850 μm can be well fitted.

On the UV/optical/NIR part of Fig. 7 we show the observed UV-optical SED (grey squares connected by a solid line). Following Eq. C.12 of Popescu et al. (2011), the UV/optical SED of the young stellar disk of NGC 4214 was dereddened using the composite attenuation, $\Delta m_1$, which is for the case of old $\sim 0$:

$$\Delta m_1 = -2.5 \log (1 - F f_i) + \Delta m_1^{disk}$$

where the first part takes into account the attenuation in the SF regions and $\Delta m_1^{disk}$ the attenuation of the diffuse component. The wavelength dependence of the escape fraction, $f_i$, is tabulated in Table A.1 in Tuffs et al. (2004). For the old stellar population we used the attenuation correction derived for the old stellar component in the model of Popescu et al. (2011) $\Delta m_1 = \Delta m_1^{disk}$. For both stellar populations we used the value of $f_i=0.40$ obtained from our best-fit model and an inclination angle of $i=44°$ (Walter et al. 2008). The SED derived in this way represents the total intrinsic stellar SED of NGC 4214 and is shown in the blue line.

We now calculate, in a similar way as in Sect. 6.2 for $SFR'$, from the intrinsic UV-to-blue luminosity the predicted value of the SFR, by applying Eq. 17 from Popescu et al. (2011), $SFR=L_{UV}/L_{\text{att,UV}}$. Using $F=0.40$ in Eq. 9, we derive $SFR=0.22 M⊙\text{yr}^{-1}$, which is a factor of 2.24 higher than
the value derived from the fitting of the dust SED ($SFR = 0.098 \, M_\odot \, yr^{-1}$). For $F = 0.20$ and $F = 0.60$, the highest and lowest values suggested by our data, the corresponding ratios are 2.51 and 2.18, respectively. If we adopt for the scale-length the maximum value allowed by the data $h_s = 1045$ pc, we obtain the best fit for $\tau_B^f = 1.2$ and $SFR' = 0.088 \, M_\odot \, yr^{-1}$, yielding $SFR = SFR'/(1-F) = 0.088/(1 - 0.40) = 0.14 \, M_\odot \, yr^{-1}$. In this case, the discrepancy with the value derived from the dereddened UV-optical data, $SFR = 0.188 \, M_\odot \, yr^{-1}$, decreases to a factor of 1.34 for $F = 0.40$ (1.50 and 1.27 for the $F = 0.20$ and $F = 0.60$, respectively).

A complete discussion of this discrepancy will be given in Sect. 7.

6.4. Gas-to-dust mass ratio

The total diffuse dust mass can be calculated from Eq. 44 of Popescu et al. (2011) ($M_{\text{dust}}^{\text{diff}} = \tau_B h_s^2 \, 0.99212 \, \text{pc}^{-2} M_\odot$). With our values of $h_s = 873$ pc and $\tau_B = 2$ we obtain $M_{\text{dust}}^{\text{diff}} = 1.5 \times 10^6 M_\odot$. This value is quite robust again changes in parameters: Choosing the largest permitted scale-length, $h_s = 1045$ pc and the corresponding best fit for the opacity, $\tau_B = 1.2$, we obtain $M_{\text{dust}}^{\text{diff}} = 1.3 \times 10^6 M_\odot$, only 13% lower. From the modelling of the HII complexes for $Z = 0.4 \, Z_\odot$, we derived dust masses of $M_{\text{dust}}^{\text{NW}} = 0.79 \times 10^5 M_\odot$ and $M_{\text{dust}}^{\text{SE}} = 0.42 \times 10^5 M_\odot$ for the NW and SE complexes, respectively. We therefore derived for NGC 4214 a total mass of dust $M_{\text{dust}}^{\text{diff}} = M_{\text{dust}}^{\text{NW}} + M_{\text{dust}}^{\text{SE}} = 1.62 \times 10^6 M_\odot$.

The total gas mass can be derived from $M_{\text{HII}} = 4.1 \times 10^6 M_\odot$ (Walter et al. 2008) and $M_{\text{H2}} = 5.1 \times 10^6 M_\odot$ (Walter et al. 2001, obtained with a Galactic conversion factor) and gives, taking into account a helium fraction of 1.36, $M_{\text{gas}} = 5.66 \times 10^6 M_\odot$. The total gas-to-dust mass ratio is then $G_{\text{dust}} = 350$.

The Galactic CO-to-H$_2$ conversion factor (X-factor, adopted here as $N$(H$_2$)/$I_{\text{CO}} = 2 \times 10^{20}$ cm$^{-2}$ (K km s$^{-1}$)$^{-1}$), most likely severely underestimates the total molecular gas mass in NGC 4214. An indication for this is e.g. the very high CI/CO ratio measured in the central region (Cormier et al. 2010) which shows that a large fraction of the CO is photo-dissociated due to the high radiation field and low dust shielding. Even though the X-factor has been notoriously difficult to determine, progress has been made in recent years mainly due to the possibility to
I. Hermelo et al.: The dust SED of dwarf galaxies

Fig. 7. SED for the total emission of NGC 4214. On the MIR/FIR/submm part we show the best-fit solution for the total emission (blue solid line) obtained as the sum of the best fit models of the HII regions (grey dashed line) from Figs. 4 and 5 and the best fit model to the diffuse emission (red dashed-dotted line) from Fig. 6, obtained for $\tau_B = 2.0$ and $SFR = 0.098 M_\odot$ yr$^{-1}$. On the UV/optical/NIR part, the grey squares and grey solid line represent the observational data, the blue-filled circles and the blue solid line are the intrinsic fluxes derived from deattenuation of the observed data points as described in Sect. 6.3. The orange dotted line corresponds to the intrinsic emission of the old stellar population (see Sect. 5.2 for details). The dotted purple line shows the intrinsic emission from the young stellar population from the UV to the optical wavelength range. The emission of the young stellar population in the B and V band was obtained after subtraction the contribution of the old stellar component (orange dotted line). The purple dashed-dotted line is the scaled emission of the young stellar population by the factor needed to predict the same $SFR$ as derived from the dust SED modelling.

derive dust masses with an increasingly better precision. This allows, together with HI and CO measurements and the assumption of a constant gas-to-dust mass ratio, to derive the ratio between total molecular gas mass and CO emission. Israel (1997) has first used this method and derived for NGC 4214 a 15-30 times higher X-factor than the Galactic value. Leroy et al. (2011) used spatially resolved data for the dust masses, derived from fits to HERSCHEL and SPITZER data, and the gas mass from HI and CO measurements for a small sample of nearby galaxies (M 31, M 33, LMC, SMC and NGC 6822). They found evidence for a strong increase of the X-factor below metallicities of 12-$\log(O/H) = 8.2$-8.4, most likely due to the dissociation of CO and the creation of extended layers of CO-free H$_2$. Leroy et al. (2011) find for NGC 6822, which has a similar metallicity as NGC 4214 ($12+\log(O/H) = 8.2$) an X-factor of 4.5 times the Galactic value. For the same galaxy, NGC 6822, and a similar method, Gratier et al. (2010) derived a higher X-factor (20 times the Galactic value). Taking this range of estimates into account, we adopt an X-factor 10 times the Galactic value as a reasonable estimate and derive for this case a gas-to-dust mass ratio of 387.

If we assume that the gas-to-dust mass ratio scales linearly with metallicity (which means that the fraction of metals incorporated in the dust is constant) we expect, based on the solar value of about 150, a value of $G_{dust}$ between 375 (for $Z = 0.4 Z_\odot$) to 500 (for $Z = 0.3 Z_\odot$).

Thus, the observed gas-to-dust ratio is very close to the expected value in the case of $Z = 0.4 Z_\odot$, and a factor 1.3 lower for $Z = 0.3 Z_\odot$. Even though we consider this discrepancy small, it could indicate that there is a still larger amount of "dark" molecular gas, not probed by the CO. We would need a conversion factor 35 times the Galactic value in order to obtain a gas-to-dust mass ratio of 500. An alternative possibility is that the dust properties in NGC 4214 are different with a higher dust extinction coefficient in the submillimeter wavelength range. This could be produced e.g. by amorphous graphite as suggested by Galliano et al. (2011) for the case of the LMC.

7. Discussion

The analysis presented in this paper enables us to draw conclusions about the physical properties of the dwarf galaxy under study. The way this can be achieved is by confirming or rejecting the basic ingredients of the models used to fit the data, from the consistency, between model predictions and data. Since our models are radiative transfer models, they contain a wealth of information regarding the distribution of stars and dust in galaxies, the clumpiness of the ISM, the dust opacity of the dust clouds, the contributions of the different phases of the ISM, and the optical properties of the dust grains, including the relative abundance of PAH molecules.

Although we can fit the FIR SED of this galaxy, the main discrepancy is that the UV emission is underpredicted with respect to our corresponding predictions for attenuation of UV light. We discuss possible causes for this discrepancy, as well as consequences for the derived physical parameters of this galaxy. We also discuss the underprediction of the 8 $\mu$m emission in the two central star-forming regions, and its implications.
7.1. Emission from PAHs at 8 \( \mu m \)

We found that the observed emission at 8 \( \mu m \) is overpredicted for the diffuse emission, and severely underpredicted for the emission from the HII regions. One reason for this could be, as we discussed in Sect. 3.1, that part of the 8 \( \mu m \) flux seen in the apertures, although powered by UV light from the star cluster, is actually likely to originate in the diffuse dust layer beyond the PDR+HII region considered by the Groves et al. (2008) model. Although it is impossible to quantify the importance of this effect, we do not think that it is entirely responsible for the discrepancies, because most of the 8 \( \mu m \) emission is clearly associated with the SF regions, as shown by the close correspondence between the 8 \( \mu m \) and Hr distribution (e.g. in the shell structure in the NW region.)

The model of Popescu et al. (2011) assumes Galactic dust properties and a fraction of PAHs in dust which is appropriate for our Galaxy. The PAH fraction in NGC 4214 might be lower given the lower metallicity (e.g. a lower PAH fraction has been found in the diffuse ISM in the SMC by Sandstrom et al. 2010). If this is the case, we can quantitatively understand the discrepancy.

A possible reason for the excess of 8 \( \mu m \) emission in the HII regions may be that the model of Groves et al. (2008) overpredicts the PAH destruction for this particular object. In the models of Groves et al. (2008) the PAH abundance is fixed to be proportional to the gas metallicity. In addition to this, it includes a parameter which controls the destruction of the PAHs in intense radiation fields. Thus, this model considers PAH destruction and assumes a lower fraction of PAHs in dust in the SF regions.

The observations of Engelbracht et al. (2008) indeed suggest that NGC 4214 might be a galaxy with an unusually high 8 \( \mu m \) emission for a given radiation field. They found a good correlation between the equivalent width at 8 \( \mu m \), EW(8 \( \mu m \)), and the ionization parameter for a set of starburst galaxies. The relation has also been confirmed for HII regions in M101 (Gordon et al. 2008). NGC 4214, one of the starburst galaxies in the Engelbracht et al. (2008) sample, deviates significantly from this correlation: it exhibits an EW(8 \( \mu m \)) a factor of 3 higher than the one corresponding to the ionization parameter. The spectra used in this analysis are not restricted to the SF regions and thus might contain emission from the diffuse medium (Engelbracht et al. 2008 do not quantify this) and therefore we cannot rigorously compare this result to our findings for the SF complexes. However, since the lines from the ionized atoms and the PAH emission come to a large extent from HII regions and their PDRs (see our Tabs. 1-3) the result of Engelbracht et al. (2008) suggests that the 8 \( \mu m \) emission in the SF regions in NGC 4214 might indeed be high.

A final possibility to explain the high 8 \( \mu m \) emission from the SF region is the ratio between neutral and ionized PAHs. The model of Groves et al. (2008) uses templates fitted to the starburst galaxies NGC 4676 and NGC 7252 with a corresponding ratio between neutral and ionized PAHs. This ratio might not be entirely appropriate for the low-metallicity galaxy NGC 4214. Ionized PAHs emit about a factor of 10 more energy in the 6-9 \( \mu m \) range than at 11-12 \( \mu m \), whereas neutral PAHs emit about the same amount in both ranges (Draine & Li 2007). Thus, a higher ionized PAH fraction could boost the predicted emission at 8 \( \mu m \) at the expense of the emission at 11-12 \( \mu m \). If we assume as an extreme case that the entire emission at 11-12 \( \mu m \) is transferred to the 8 \( \mu m \) band, we can increase the emission for our model spectrum at 8 \( \mu m \) by a factor of ~2. Thus, we could indeed improve the agreement between data and model, although some discrepancy would remain.

7.2. The UV emission illuminating the diffuse dust

In Section 6 we found that there is tension between the observed surface brightness of the disk in the submm and the observed flux of the galaxy in the non-ionising UV in the sense that, although the FIR SED can be fitted, the UV emission is underpredicted by a factor ~2-3 with respect to our corresponding predictions for attenuation. Here we discuss the plausibility of such an escape fraction and study further possibilities to explain the differences between model and data.

7.2.1. Escape of unattenuated UV radiation from NGC 4214

In starburst galaxies, it has been previously observed that a fraction of the UV luminosity can escape from the galaxies without heating the dust, mainly due to the porosity of the ISM created by the energy input of massive stars and SNe which in the extreme case leads to (super)bubbles and galactic winds. Oey et al. (2007) showed that starburst galaxies present a low diffuse Hr emission consistent with an expected escape fraction of ionizing photons of 25% from the galaxy.

Other studies show that the escape of ionizing radiation (and therefore non-ionizing as well) could be much lower: Leitherer et al. (1995) pointed out that 3% of the intrinsic LyC photons escape from a set of starburst galaxies; Grimes et al. (2009) found an even lower (<1%) fraction for local starburst galaxies, and Siana et al. (2007) found a low escape fraction for low (substellar) metallicity starburst galaxies (<8%).

However, the detection of the escaping photons might be determined by the geometry and orientation of the observations if holes and open channels are the medium that the radiation uses to escape from the galaxy (Clarke & Oey 2002, Zastrow et al. 2011). Besides, the escape fraction can be affected by the internal properties of galaxies, depending sensitively on the covering factor of clumps, and the density of the clumped and interclumped medium (Fernandez & Shull 2011).

Conditions that are favorable for an escape are likely to be given in starburst dwarf galaxies which generally show large bubbles and shell structures (Martin 1998) – similar to what we are seeing in the center of NGC 4214 – that would make the ISM more porous and prone to enable the UV radiation to escape. The simulations of Wise & Cen (2009) showed that an escape fraction as high as 25-80% can be expected due to the irregular morphology of the dwarf galaxies with a clumpy ISM. There are observational confirmations of such an escape. Cormier et al. (2012) found evidence for a escape of 80% of the non-ionizing UV-radiation from the low metallicity Haro 11 and Bergvall et al. (2006) an escape fraction of the Lyman continuum radiation of 4-10% in the same object. Zastrow et al. (2011) have detected an ionized cone above a shell structure in the starburst galaxy NGC 5253 suggesting that ionizing radiation could be escaping from this galaxy. In the presence of such channels we would expect that not only ionizing, but also non-ionizing radiation escape from the galaxies without being affected by dust.

The geometry of the central SF regions, especially in the case of the NW region, suggests that bubbles have been already created in NGC 4214. We can make an estimate of how much such a process could affect NGC 4214 by assuming that the entire UV luminosity from these regions leaves the galaxy unattenuated. The UV luminosity of the two main HII regions represent
20% of the total UV luminosity of NGC 4214. Therefore, about 20% of the total UV luminosity possibly does not contribute to the dust heating and should be subtracted when converting into the $SFR$ heating the dust in the disk. This fraction is close to the lower limit of the observed discrepancy and thus might be able to explain a considerable part of it.

7.2.2. A different geometry of dust and stars in NGC 4214

In our modeling we have assumed that NGC 4214 is a scaled-down version of the model spiral galaxy used in Popescu et al. (2011). However the differences in the geometry for the spiral and dwarf galaxies can affect the comparison of the data with the model of Popescu et al. (2011).

The relative scale-heights and scale-lengths of the dust and the stars are derived from a sample of edge-on spiral galaxies (Xilouris et al. 1999). However, the geometry of dwarf galaxies is known to be different from that of larger spiral galaxies. In particular, their stellar disks are thicker in comparison to their diameter (e.g. Hunter & Elmegreen 2006). This is not unexpected because the scale-height depends on the mass surface density, which determines the gravitational potential in the vertical direction and the velocity dispersion. Both are generally similar in dwarf galaxies and in spiral galaxies, therefore the absolute value of the vertical scale-height is expected to be similar, and, since they are smaller than spiral galaxies, the ratio between scale-height and scale-length becomes larger. The gas scale-height is even higher in absolute terms than in spiral galaxies (Brinks et al. 2002). Thus, we would expect higher ratios between the vertical scale-heights and the radial scale-lengths than the one assumed in the model. In NGC 4214 Maíz-Apellániz et al. (1999) estimates the vertical stellar scale-height to be about 200 pc, i.e. about 1/4 to 1/5 of the radial scale-length. This is at least a factor of 3 higher than the ratio assumed in the Popescu et al. (2011) model. However, the effects of a difference in the ratio between scale-height and scale-length are not expected to be very large as long as the relative scale ratios between stars and dust are the same.

Another possible, albeit speculative, difference between the model and the real geometry could be a non-central position of the NW and SE SF regions. Since these regions are dominating the young SF activity in the galaxy and are very likely responsible for a large fraction of the UV emission, their possible position above or below the galactic disk would have an important impact on the dust heating, whereas in large galaxies such an asymmetry is unlikely due to the high number of SF regions.

The geometry of the galaxy can also affect the way we are using the attenuation in the disk. The model for attenuation assumes that the star-forming complexes are distributed in a thin disk, with a radially decreasing exponential distribution. If instead NGC 4214 had most of the star formation occurring in its center, then the model for attenuation in the UV may overpredict the attenuation if the high local concentration of stars has the effect of breaking up the dust layer.

7.2.3. An extended dust component

If the dust is more extended compared to the stellar disk than what is assumed in the model, such an extended dust component will be relatively cold and emit more in the submillimeter. By including such a component we would therefore be able to use a higher value of $SFR$ for the rest of the dust and decrease the discrepancy with the observed UV emission. Furthermore, an extended, cold dust component could explain the missing flux at the long wavelengths. Popescu et al. (2002) have found indications of such an extended dust component with ISO data in dwarf galaxies, however their data lacked the spatial resolution to directly measure its spatial extent. In order to test whether there are indications for an extended dust component, we derived the radial scale-lengths from SPIRE 250, 350 and 500 $\mu m$ bands. The rather irregular distribution of the dust emission did not allow us to define elliptical isophotes at all galactocentric radii, instead we derived the median values with the isophotal elliptic annuli defined in the g-band image. By carrying out a least square-fit to the radial distribution of these median values, we derived scale-lengths of 835 pc, 920 pc and 1067 pc for SPIRE 250, 350 and 500 $\mu m$, respectively. The increase of the scale-lengths from shorter to longer wavelengths is expected because of the decrease of the dust temperature towards the outer parts of the galaxy. The longest wavelength (SPIRE 500 $\mu m$) best represents the scale-length of the dust distribution but most likely still underestimates it.

The model of Popescu et al. (2011) adopts a dust scale-length of 1.406 x $h_\star$. With $h_\star = 873$ pc this would predict a dust scale-length of 1227 pc, which is slightly higher than the measured scale-length at SPIRE 500 $\mu m$ band. Thus, although we cannot exclude the presence of an extended dust component because the dust scale-length can be longer than that at SPIRE 500 $\mu m$ band, we do not find any clear evidence for its presence.

7.2.4. Different dust properties

Until now we have mainly discussed different geometrical scenarios for explaining the discrepancies we find in the UV. There is however another possibility, that the submm mass absorption coefficient of grains, as specified by the Weingartner & Draine (2001) model and as used in the radiation transfer model of Popescu et al. (2011), underestimates the true mass absorption coefficient of the grains in the submm, leading to a lower dust surface densities and a lower disk opacity in the UV for the observed submm brightness of the diffuse dust. This is a solution that unfortunately is largely degenerate with the assumed geometry of stars and dust. Because of this, and the lack of independent constraints on the existence of such a dust model, we cannot draw any conclusion on this issue.

7.2.5. Physical implications

In the previous subsections we discussed a few possibilities that might have caused the discrepancy in the predicted level of UV emission. Probably the most likely scenario is that dynamical effects associated with a recent burst of SF activity responsible for the central SF complexes has punched holes through the diffuse dust layer, through which the UV photons leaving the SF regions can escape the galaxy without interacting with the diffuse dust. This would be a natural outcome of a non-steady state behaviour of SF activity in dwarf galaxies, in which we may be observing NGC 4214 in a post starburst phase, where the star clusters are no longer fully cocooned by dust, but to the contrary have evolved to the point where SN and wind activity have cleared the dust in the ISM above the location of the starburst.

The existence of different grain properties is also plausible, though difficult to distinguish from the other scenarios. This would increase the inferred gas-to-dust mass ratios compared to the radiation transfer model predictions, bringing it closer to the values expected from the observed metallicity of NGC 4214.
Furthermore, dust grains with a higher submillimeter emissivity and a flatter frequency dependence would be able to better explain the dust emission at long wavelengths (850 µm) where our model presently underpredict the observations by 34%.

8. Summary and conclusions

We have analysed and modelled the dust SED of the nearby starbursting dwarf galaxy NGC 4214. Due to its proximity we were able to derive the dust SED separately for the emission from the two major massive SF regions and for the diffuse dust. For the first time this analysis was done from the perspective of a self-consistent radiation transfer calculation constrained by the observed SEDs of spatially separated components on resolved maps. In making predictions for the UV/optical-FIR/submm SEDs of these components this analysis quantitatively takes into account the level and colour of UV/optical radiation fields incident on both pc-sized dusty structures in the SF complexes and on dust grains distributed on kpc scales in the diffuse ISM, illuminated by a combination of UV light escaping from the SF regions and the ambient optical radiation fields, as constrained by UV/optical photometry of the galaxy. The overall analysis was done using the model predictions and the formalism from Popescu et al. (2011), while for the detailed modelling of the two central SF complexes we used the model of Groves et al. (2008). The large amount of ancillary data and results from previous studies allowed us to constrain a major part of the input parameters of the models.

We achieved a good agreement between data and models, both for the diffuse dust emission and the dust in HII+PDR regions. For the comparison with the dust emission from HII+PDR regions we could constrain from observations basically all input parameters (metallicity, age of star cluster, external pressure, heating capacity and covering factor) with the exception of the gas column density of the PDR. We achieved satisfactory fits for both SF regions with the exception of the 8 µm data points. Possible reasons for this discrepancy are that the model assumptions (PAH abundance and destruction) are not completely adequate for the case of NGC 4214 or that NGC 4214 has an unusually high emission at 8 µm for its metallicity and radiation field, which is supported by other studies (Engelbracht et al. 2008).

We could fit the diffuse dust SED satisfactorily, but we inferred that the UV emission was severely underpredicted with respect to the observed, deattenuated diffuse UV flux. We have discussed different explanations for this discrepancy (escape of UV emission, geometrical effects, a very extended dust disk and different dust properties). The most plausible one is that part (30-70%) of the UV radiation that escapes from HII+PDR regions leaves the galaxy unattenuated and is thus not participating in the heating of the diffuse dust, most likely due to a porous ISM.

We derived a global gas-to-dust mass ratio of 350–390, close to the value expected from the metallicity of NGC 4214 (Z = 0.3 – 0.4 Z⊙) of 375 – 500.

In summary, this is the first time a full radiation transfer analysis constrained by the observed SEDs of spatially separated components has been done for a dwarf galaxy. Corresponding radiation transfer studies of resolved star-forming dwarf galaxies but with different inclinations and evolutionary states to NGC 4214 may allow to distinguish between the alternative physical scenarios shaping the panchromatic SEDs of these systems.

Acknowledgements. We thank the referee, F. Galliano, whose comments helped to improve the clearness of the manuscript, Joerg Fischera for insightful discussions about the ISM and Médéric Boquien for help with the Herschel data.
