Stringent limits on top-quark compositeness
from $t\bar{t}$ production at the Tevatron and the LHC

(Dated: May 11, 2014)

If the top quark is a composite state made out of some constituents, its interaction with the gluon will be modified. We introduce the leading effective operators that contribute to the radius and anomalous magnetic moment of the top quark and study their effect on the cross section for $t\bar{t}$ production at the Tevatron and the LHC. Current measurements of the cross sections set a stringent limit on the scale of compositeness. This limit is comparable to similar limits obtained for light quarks and those from electroweak precision measurements. It can be used to constrain the parameter space of some composite Higgs models.

PACS numbers: 14.65.Ha,12.60.Rc,13.85.Lg

I. MOTIVATIONS

Whether the top quark is a point-like particle or an extended object is a question that can now be addressed thanks to the large number of them produced at the LHC and the Tevatron. The most recent, combined measurement of the cross section for $t\bar{t}$ production is in good agreement with the most up-to-date theoretical prediction within the standard model (SM) and this result can be used to put constraints on the compositeness of the top quark.

Whereas in the SM the top quark—as well as all other fundamental particles—has no structure, various extensions of the SM are based on some form of compositeness: in particular, the composite Higgs boson [1, 2], as well as its partial compositeness implementation [3, 4], but also models inspired by the littlest Higgs [5] and technicolor [6] assume the existence of a strongly interacting sector, the SM particles being either composite object themselves or mixing with particles which are. The top quark, it being the heaviest of all states, is the best candidate for searching for possible signatures of such compositeness. The problem has been previously addressed in [7] and more recently in [8–15]. We discuss in some detail the implications of the limits we find on possible extensions to the SM in the last section.

A. Composite top quark and strong interactions

Compositeness can manifest itself in various ways. We take the most direct approach and look into what effect a finite extension of the top quark has on its interaction with the gauge bosons. In the case most relevant for collider physics, we can write two form factors $F_1(q^2)$ and $F_2(q^2)$ modifying the vertex between the top quark and the gluon as

$$g_s I \left[ \gamma^\mu F_1(q^2) + \frac{i\sigma^{\mu\nu}q_\nu}{2m_t} F_2(q^2) \right] G_\mu^A,$$

where $g_s$ is the strong $SU(3)_C$ coupling constant, $G_\mu^A = T_A G_\mu$ is the gluon field, $T_A$ are the $SU(3)_C$ group generators, $q^\mu$ is the momentum carried by the gluon, $t$ denotes the top quark field and $\sigma^{\mu\nu} = i[\gamma^\mu, \gamma^\nu]/2$. The interaction in eq. (1) is the most general after assuming that the vector-like nature of the gluon-top quark vertex is preserved by the underlying dynamics giving rise to the composite state.

As originally pointed out for the case of electromagnetic interactions [16], the physics of the form factors in eq. (1) is best represented by the combinations

$$G_E(q^2) = F_1(q^2) + \frac{q^2}{4m_t^2} F_2(q^2) \quad \text{and} \quad G_M(q^2) = F_1(q^2) + F_2(q^2),$$

which are (in the Breit frame) the Fourier transform of, respectively, the chromo-electric and -magnetic charge densities $\rho_c$ and $\mu_{\rho_m}$ of, in our case, the top quark. For an extended object these densities are not Dirac $\delta$-functions and can...
be expanded. To the leading order, we thus obtain a first momentum (the chromo-magnetic moment \(\mu\)):

\[
G_M(q^2) = \frac{2}{\pi} \int dr \, r^2 j_0(qr) \mu \rho_m(r) \simeq \mu + \cdots
\]

(3)

from the chromo-magnetic charge density, and a second momentum (the squared mean radius \(\langle r^2 \rangle\)):

\[
G_E(q^2) = \frac{2}{\pi} \int dr \, r^2 j_0(qr) \rho_c(r) \simeq 1 - \frac{q^2}{6} \langle r^2 \rangle + \cdots
\]

(4)

from the chromo-electric charge density. In eqs. (3)–(4), \(j_0(x) = \sin x / x\) represents the spherical Bessel function of order zero and the (non-relativistic) charges \(\rho_c\) and \(\rho_m\) are related to the four-current as

\[
j^{\mu}(r) = (g_s \rho_c(r), \mu \, \bar{\sigma} \times \nabla \rho_m(r)) .
\]

(5)

The two parameters \(\mu\) and \(\langle r^2 \rangle\) are traditionally used in nuclear physics to characterize the finite extension of nucleons and other extended objects.

Form factors are just a way of organizing the perturbative expansion. An alternative and perhaps better approach is effective field theory. In this language the expansion is given in terms of operators invariant under the underlying symmetries that are added to the SM lagrangian. These operators have dimension higher than four and are suppressed by negative powers of the new physics scale to get the required dimension.

In this work we use the effective field theory approach and consider the contributions given by \(SU(3)C \times U(1)_{em}\) invariant effective operators to the top-quark form factors introduced in eq. (3). The leading contributions come from the following two higher dimensional operators:

\[
\hat{O}_1 = g_s C_1 \frac{2}{m_t^2} \bar{\tau}^{\mu} T_A t D^\nu G^{A}_{\mu\nu} \quad \text{and} \quad \hat{O}_2 = g_s C_2 \frac{2}{m_t^2} \bar{t} \gamma^{\mu} T_A t G^{A}_{\mu\nu}
\]

(6)

where \(D^\nu G^{A}_{\mu\nu} = \partial^\nu G^{A}_{\mu\nu} + g_s f_{ABC} G^{\nu B} G^{\mu C}\), \(G^{A}_{\mu\nu} = \partial_\mu G^{A}_{\nu} - \partial_\nu G^{A}_{\mu} + g_s f_{ABC} G^{B}_{\mu} G^{C}_{\nu}\) is the gluon field strength tensor, \(f_{ABC}\) are the \(SU(3)C\) structure constants and \(v = 174\) GeV is the electroweak (EW) symmetry breaking vacuum expectation value. In eq. (6) the operator \(\hat{O}_1\) and \(\hat{O}_2\) are, respectively, of dimension six and five. We limit ourselves to the \(CP\)-conserving case and the dimensionless coefficients \(C_1\) and \(C_2\) are taken to be real. Left- and right-handed fermion fields enter symmetrically. The operator \(\hat{O}_1\) gives the leading \(q^2\) dependence to \(F_1\) while \(\hat{O}_2\) gives the \(q^2\)-independent term of \(F_2\):

\[
F_1(q^2) = 1 + C_1 \frac{q^2}{m_t^2} + \cdots \quad \text{and} \quad F_2(0) = 2 C_2 \frac{v}{m_t} .
\]

(7)

Operators of higher dimensions can in general contribute—they gives further terms in the expansion of the form factors—but their effect should be suppressed. We have checked that possible corrections due to dimension 8 operators such like

\[
G_{\mu\nu} G^{\mu\nu} q \bar{H} T_R
\]

(8)

are suppressed as long as the coefficients are taken to be \(O(C_{1,2}^2)\).

The form of the coefficients in front of the operators in eq. (6) is conventional and dictated, in our case, by the analogy with the electromagnetic form factors. In addition, the operator \(\hat{O}_2\) is written for convenience with an extra factor \(v / m_t\) because it can be thought as coming, after EW symmetry breaking, from a dimension six \(SU(3)C \times SU(2)_L \times U(1)_Y\) gauge invariant operator that includes the Higgs boson field.

Replacing the expressions of the form factors obtained in eq. (7) into eq. (2), we can obtain an estimate of the radius and chromo-magnetic moment of the top quark using the same formulas that apply in the electromagnetic case. We have that

\[
\langle r^2 \rangle = -6 \frac{d G_E}{d q^2} \Bigg|_{q^2=0} \text{ and } \mu = G_M(0) ,
\]

(9)

where \(\mu\) is the chromo-magnetic moment of the top quark measured in units of \(g_s / 2m_t\).

The aim of this work is to give an estimate of the size of these quantities by constraining the values of the dimensionless coefficients \(C_1\) and \(C_2\) using the available LHC public data on the \(t\bar{t}\) total production cross section \(\sigma(pp \rightarrow t\bar{t})\) and those for the \(\sigma(pp \rightarrow t\bar{t})\) from the Tevatron. In addition, we also include constraints from data on
spin correlations of the top quarks at the LHC. The results will be used in the last section where we will translate the bounds on $C_1$ and $C_2$ into limits on new physics scales in the framework of some specific models.

The finite extension of the source generating the terms in eq. (9) arises because of the radiative corrections of the parton-level processes as well as because of the presumed compositeness. In order to disentangle these two contributions we assume that the former is included in the SM cross section computed at the next-to-leading order (NLO) and beyond (for the most recent exact computation at the NNLO and NNLL, see [17] and citations therein), leaving $C_1$ and $C_2$ to encode only effects intrinsically due to compositeness.

The operators $\hat{O}_1$ and $\hat{O}_2$ enter at tree level into the computation of the $tt$ production cross section through gluon fusion and quark-antiquark annihilation. The first channel is the dominant one at the LHC while the second is dominant at the Tevatron. At tree level, in addition to the usual SM QCD Feynman diagrams, one has to take into account the contributions coming from the new interactions as depicted in Fig. 1 and Fig. 2. The diagram (f) of Fig. 1 is a contribution not present in the SM and due to the presence of the operators $\hat{O}_1$ and $\hat{O}_2$: it represents the effective interaction of two gluons and the $\bar{t}t$ pair. Notice that the contribution of the operator $\hat{O}_1$ cancels out in the sum of the gluon fusion amplitudes.

Following the effective field theory approach, one has to write down all possible dimension five and six operators that contribute to the $tt$ production cross section. It is possible to show [18] that—by rearrangement and field redefinitions using the equations of motion—out of all possible operators that contribute to this process only three are independent, namely $\hat{O}_1$, $\hat{O}_2$ in eq. (6) and a set of four-fermion operators. If we further assume the same coefficient in front of the four-fermion operators involving two top quarks and two light quarks of different flavors, then these four-fermion operators too can be rewritten, by means of the equations of motion, in terms of the operator $\hat{O}_1$. We are thus left with just the two operators $\hat{O}_1$ and $\hat{O}_2$ in eq. (6). Notice that in general, the whole set of four fermion operators entering in the dimension 6 SM effective lagrangian is larger and cannot be rewritten as $O_1$.

Anomalous couplings and top quark production has been discussed by several authors [11], most recently in [12] (and [13], which came out while we were finishing this work). The anomalous magnetic moment of these references corresponds to the coefficient $C_2$ of the chromo-magnetic operator in eq. (6). Ref. [14] follows an approach similar to ours but with different and less stringent results. The effect on $\bar{t}t$-production of $\hat{O}_2$ (together with the four-fermion operators) has been studied in [15] in the context of non-resonant new physics at the Tevatron and the LHC. See [19] for and updated version.

In the low-energy regime, data on $B$-physics can be affected by the operators in eq. (6). In particular, the operator $O_2$ contributes to the matching condition of the Wilson coefficient of the chromo-magnetic operator between the quark $b$ and $s$. The latter operator mixes with the electro-magnetic dipole moment operator

$$e m_b \bar{b} \sigma^{\mu\nu}(1 + \gamma_5) s F_{\mu\nu},$$

(10)
which give rise to the transition $b \to s\gamma$. Even though data on the branching fraction \cite{20} can in principle be used to set limits on the coefficient $C_2$, the estimates in literature give either too small an effect \cite{21} or one with large uncertainties \cite{22}. For this reason we do not use these limits.

\section{Methods}

\subsection{Monte Carlo implementation}

In order to study new physics effects on $t\bar{t}$ production cross sections (and spin correlations) at the LHC and Tevatron, we have first used FEYNRULES \cite{23} to implement our model, which has been defined to be the SM with the addition of the two effective operators $\mathcal{O}_1$ and $\mathcal{O}_2$ of eq. (6). FEYNRULES provides the Universal FeynRules Output (UFO) with the Feynman rules of the model. The UFO is then used by MadGraph 5 \cite{24} (MG5) to compute the production cross section, that we denote by $\sigma_{\text{MG5}}(C_1, C_2)$.

The main $t\bar{t}$ production channel at LHC is given by gluon fusion and the associated Feynman diagrams are those in Fig. 1. Other sub-leading channels are given by quark-antiquark annihilation, whose diagrams are depicted in Fig. 2. MG5 computes the square of the amplitude for each single channel and then convolutes the result with the probability distribution functions (pdf) of the partons inside the proton in order to obtain the total $pp \to t\bar{t}$ production cross section. The default set of pdf used is CTEQ6L1.

The partonic level result thus obtained can be compared with the partonic experimental cross section that is extracted by the experimental collaborations from the fully hadronized cross section—which is what is actually measured at the colliders.

We compute, using MG5, $\sigma_{\text{MG5}}(C_1, C_2)$ for three different values of the center of mass energy (7, 8 and 14 TeV), varying the absolute values of both $C_1$ and $C_2$ in a range that goes from 0 to 0.1. These different values of $\sigma_{\text{MG5}}(C_1, C_2)$ will be used to obtain limits on the coefficients $C_1$ and $C_2$ by comparing the MG5 computation with the measured cross section at the center-of-mass (CM) energy $\sqrt{s} = 7$ and 8 TeV and the expected result at 14 TeV, as discussed in the next section.

By proceeding in the same way, we have also computed the $t\bar{t}$ production cross section at the Tevatron and compared it with the measured cross section at the CM energy $\sqrt{s} = 1.98$ TeV. In this case, the main $t\bar{t}$ production channel is given by quark-antiquark annihilation and the associated Feynman diagrams are those depicted in Fig. 2. As we shall see, in this case we obtain a particular stringent bound on $C_1$.

\subsection{Statistical analysis}

The quantity used to obtain 95\% confidence level (CL) limits on the coefficients $C_1$ and $C_2$ is the cross section $\Delta\sigma_{\text{exp}}$, which is defined to be the difference between the central value of the measured cross section $\bar{\sigma}_{\text{exp}}$ and that of the SM theoretical value $\bar{\sigma}_{\text{th}}$:

$$\Delta\sigma_{\text{exp}} = \bar{\sigma}_{\text{exp}} - \bar{\sigma}_{\text{th}}.$$  \hspace{1cm} (11)

The uncertainty is given by summing in quadrature the respective uncertainties:

$$\sqrt{(\delta\sigma_{\text{exp}})^2 + (\delta\sigma_{\text{th}})^2}.$$  \hspace{1cm} (12)

Using the cross sections $\sigma_{\text{MG5}}(C_1, C_2)$ calculated with MG5 we compute the value of the cross section coming from new physics $\Delta\sigma_{\text{MG5}}(C_1, C_2)$ as

$$\Delta\sigma_{\text{MG5}}(C_1, C_2) = \sigma_{\text{MG5}}(C_1, C_2) - \sigma_{\text{MG5}}(0, 0).$$  \hspace{1cm} (13)

The quantity $\Delta\sigma_{\text{MG5}}(C_1, C_2)$ represents the contribution to the cross section coming from the interference between SM leading order and new physics diagrams. Terms coming from the interference between new physics and higher order QCD diagrams are not included in this approximation.

Values of $C_1$ and $C_2$ for which $\Delta\sigma_{\text{MG5}}(C_1, C_2)$ is more than two standard deviations from $\Delta\sigma_{\text{exp}}$, namely

$$\Delta\sigma_{\text{MG5}}(C_1, C_2) > \Delta\sigma_{\text{exp}} + 2\sqrt{(\delta\sigma_{\text{exp}})^2 + (\delta\sigma_{\text{th}})^2},$$  \hspace{1cm} (14)

or

$$\Delta\sigma_{\text{MG5}}(C_1, C_2) < \Delta\sigma_{\text{exp}} - 2\sqrt{(\delta\sigma_{\text{exp}})^2 + (\delta\sigma_{\text{th}})^2},$$  \hspace{1cm} (15)

can be considered excluded at 95\% CL.
### III. RESULTS

#### A. SM cross section

A typical one-loop radiative correction to the vertices gives a contribution to the top quark radius $O(\alpha_s/2\pi m_t^2)$. Because the effect of compositeness is of the same order, the SM theoretical amplitude $\sigma_{th}$ used for obtaining the exclusion limits, as explained in the previous section, must contain at least NLO contributions which include these corrections as well as those coming from initial and final state radiation.

Production of top quark pairs at hadron colliders is a challenging computation that has been pursued for many years and is now available at the next-to-next-to-leading order (NNLO) \[17\]. In addition, the soft gluon re-summation for the same process is known at the next-to-next-to-leading logs (NNLL) order necessary for the matching \[25\]. Following \[17\] we take, for a top-quark mass of 172.5 GeV, the following values for the cross section at the LHC for, respectively, the CM energy $\sqrt{s} = 7$ and 8:

$$
\sigma_{th}(pp \to t\bar{t}) = \begin{cases} 
176.25^{+4.6}_{-4.4} \text{ (scale)} & +4.8 \text{ (pdf) pb (LHC@7)} \\
251.68^{+6.4}_{-6.6} \text{ (scale)} & +6.3 \text{ (pdf) pb (LHC@8)} 
\end{cases},
$$

(16)

where the first uncertainty is due to the residual scale dependence and the second to the pdf of the partons which are taken from the MSTW200NNLO68CL set \[26\]. At the Tevatron, for a CM energy $\sqrt{s} = 1.98$ TeV, the same reference \[17\] gives

$$
\sigma_{th}(p\bar{p} \to t\bar{t}) = 7.35^{+0.11}_{-0.21} \text{ (scale)} +0.17_{-0.12} \text{ (pdf) pb (Tevatron)}.
$$

(17)

The size of the overall uncertainty of these results—summing the square of the two errors—is a substantial improvement with respect to the NLO result.

#### B. Current data and bounds: LHC and Tevatron

The cross section for the production of top quark pairs has been measured at LHC and Tevatron for their respective energy range.

![Graph](image)

**FIG. 3:** Constraints on the coefficients $C_1$ and $C_2$ from data at the LHC at $\sqrt{s} = 7$ TeV. On the left: the limit on $C_1$ with $C_2 = 0$. On the right, the limit on $C_2$ with $C_1 = 0$. The horizontal dashed black line represents the experimental central value. The yellow (green) band represents 2(1) $\sigma$ uncertainties. The red lines are the expected limits at 1 and 2 $\sigma$ level. The thick black line is the cross section in the presence of the new operators at sampled values of the coefficients $C_i$.

The best current measurements at the LHC of the cross section $\sigma_{exp}(pp \to t\bar{t})$ combining the various channels at
the CM energy of $\sqrt{s} = 7$ TeV, for a top-quark mass of 172.5 GeV, is

$$\sigma_{\text{exp}}(pp \to t\bar{t}) = \begin{cases} 177.0 \pm 3 \text{ (stat)} \pm 7 \text{ (syst)} \pm 7 \text{ (lumi)} \text{ pb} & (\text{ATLAS}) \\ 165.8 \pm 2.2 \text{ (stat)} \pm 10.6 \text{ (syst)} \pm 7.8 \text{ (lumi)} \text{ pb} & (\text{CMS}) \end{cases}$$

(18)

for, respectively ATLAS [27] and CMS [28].

A combination of ATLAS and CMS results is available [29] for an integrated luminosity of up to 1.1 fb$^{-1}$:

$$\sigma_{\text{exp}}(pp \to t\bar{t}) = 173.3 \pm 10.1 \text{ pb}$$

(19)

with an overall uncertainty of 5.8% which we will use in our analysis to set the limits.

Fig. 3 show the limits coming from LHC@7 on the coefficients $C_1$ and $C_2$ obtained by means of the above experimental result and the theoretical computation in eq. (16).

In Fig. 3 as well as in the following figures, the black line with dots represents the cross section $\Delta \sigma_{\text{MG5}}$ which includes the contributions of the operators $\hat{O}_1$ and $\hat{O}_2$. The yellow (green) bands represents the cross section $\Delta \sigma_{\text{exp}}$ with its error at 2(1)$\sigma$ level. Finally, the horizontal red lines represent the expected limits (at the 1 and 2$\sigma$ level) which are obtained by identifying the central value of the experimental data $\bar{\sigma}_{\text{exp}}$ with the central value of the theoretical prediction $\bar{\sigma}_{\text{th}}$.

The best current measurements of the cross section $\sigma_{\text{exp}}(pp \to t\bar{t})$ at the CM energy of $\sqrt{s} = 8$ TeV for a top-quark mass of 172.5 GeV is

$$\sigma_{\text{exp}}(pp \to t\bar{t}) = \begin{cases} 237 \pm 1.7 \text{ (stat)} \pm 7.4 \text{ (syst)} \pm 7.4 \text{ (lumi)} \pm 4.0 \text{ (beam energy)} \text{ pb} & (\text{ATLAS [30]}) \\ 227 \pm 3 \text{ (stat)} \pm 11 \text{ (syst)} \pm 10 \text{ (lumi)} \text{ pb} & (\text{CMS [31]}) \end{cases}$$

(20)

for, respectively, an integrated luminosity of 5.8 fb$^{-1}$ at ATLAS and 2.4 fb$^{-1}$ at CMS, in both cases considering events with dilepton final states.

Lacking a combined value, we consider the experimental value of ATLAS [30], which has smaller uncertainties, to set the limits; the theoretical value is taken from eq. (16). Fig. 3 shows the result in this case. Notice that improved limits with respect to the previous ones at $\sqrt{s} = 7$ TeV are mainly due to the lower central value of the experimental data. This is made clear by the comparison with the expected CL (the red horizontal lines in Fig. 4).

Combined data from CDF and D0 at the Tevatron [32] give the following cross section at the CM energy of $\sqrt{s} = 1.96$ TeV up to an integrated luminosity of 8.8 fb$^{-1}$:

$$\sigma_{\text{exp}}(p\bar{p} \to t\bar{t}) = 7.65 \pm 0.42 \text{ pb}$$

(Tevatron).

(21)
FIG. 5: Constraints on the coefficients $C_1$ and $C_2$ from data at the Tevatron at $\sqrt{s} = 1.96$ TeV. On the left, limit on $C_1$ with $C_2 = 0$. On the right, limit on $C_2$ with $C_1 = 0$. The horizontal dashed black line represents the experimental central value. The yellow (green) band represents 2(1)$\sigma$ uncertainties. The red lines are the expected limits at 1 and 2$\sigma$ level. The black line is the cross section in the presence of the new operators at sampled values of the coefficients $C_i$.

Fig. 5 show the limits coming from Tevatron on the coefficients $C_1$ and $C_2$ we obtain by means of the above experimental result and the theoretical computation in eq. (17). The data from the Tevatron are particularly stringent in the case of the operator $\hat{O}_1$ because of the kinematical configuration that prefers the $qq \rightarrow t\bar{t}$ channel which is, in turn, most sensitive to that operator.

C. Future bounds: LHC at $\sqrt{s} = 14$ TeV

FIG. 6: Possible constraints on the coefficients $C_1$ and $C_2$ from data at the LHC at $\sqrt{s} = 14$ TeV. On the left, limit on $C_1$ with $C_2 = 0$. On the right, limit on $C_2$ with $C_1 = 0$. The horizontal dashed red line represents the experimental central value. The other red lines are the expected limits at 1 and 2$\sigma$ level. The black line is the cross section in the presence of the new operators at sampled values of the coefficients $C_i$. 
If we assume that the experimental uncertainty will remain around 5%—it is difficult to imagine doing better than this—we can plot the expected limits at the LHC when the CM energy will be $\sqrt{s} = 14$ TeV by fixing the experimental central value to coincide with the theoretical cross section:

$$\sigma_{tt}(p\bar{p} \rightarrow t\bar{t}) = 953.6^{+22.7\text{(pdf)}}_{-43.9\text{(scale)}}^{+16.2\text{(pdf)}}\text{ pb (LHC@14)} \quad [17].$$

(22)

As depicted in Fig. 6, the increase in energy improves the limits with respect to what was to be expected at the LHC at lower CM energies. However, the study at 14 TeV does not modify in a significative manner the overall limits because the actual experimental value at 8 TeV turned out lower than the theoretical value and therefore yielded a better than expected limit.

D. Differential cross section

![Graph](image)

FIG. 7: Left side: Differential cross section in bins of $m_{t\bar{t}}$ for LHC at 7 TeV. In the first bin, the total cross section. In color, the changes bin by bin for different values of the coefficient $C_1$. Right side: Limit on the coefficient $C_1$ (see the text).

Even though the differential cross section for $t\bar{t}$ production contains, in principle, extra information that can be used to set limits on the compositeness of the top quark, we find that the current experimental uncertainties are too large to significantly improve the best limits we found by considering the total cross section.

The best case occurs for the cross section as a function of the invariant mass $m_{t\bar{t}}$ for the LHC with data at $\sqrt{s} = 7$ TeV [33] and for the coefficient $C_1$. Fig. 7 plots this cross section in bins and shows the experimental value with its error and the variation for different values of the coefficient $C_1$.

To set limits combining the total cross section $\sigma_{\text{tot}} = \sigma_{tt}$ and the relative differential cross section $\sigma_{\text{dif},i} = (1/\sigma_{tt})d\sigma_{tt}/dm_{t\bar{t}}$ in each bin $i$, we evaluated a $\chi^2$ function as:

$$\chi^2 = \left[\frac{\sigma_{\text{exp}} - \sigma_{\text{th}}}{\delta(\sigma_{\text{tot}})}\right]^2 + \sum_{i=0}^{N_{\text{bins}}} \left[\frac{\sigma_{\text{exp}} - \sigma_{\text{th}}}{\delta(\sigma_{\text{dif},i})}\right]^2,$$

(23)

where $\delta(\sigma)$ refers to the squared sum of the experimental and the theoretical uncertainties on the respective $\sigma_{\text{tot}}$ and $\sigma_{\text{dif},i}$, and the suffix th refer to the theoretical prediction. This theoretical prediction is given by the NLO+NLL calculation [34] plus the contribution from new physics depending on the value of $C_1$, evaluated generating events with MADGRAPH and then PYTHIA [35].

This quantity $\chi^2$ is evaluated for each of the considered values of $C_1$ and compared with a distribution of $\chi^2$ values obtained generating 10^3 pseudo-experiments allowing the measured values to fluctuate following a gaussian distribution $G(\sigma, \delta(\sigma))$. A value of $C_1$ was considered excluded at 95% C.L. if less than 5% of the pseudo-experiments resulted in a $\chi^2$ value larger than the one for the given value of $C_1$.

To get an approximate 95% C.L. exclusion limit on $C_1$, the obtained values of $\chi^2$ as a function of $C_1$ were interpolated as shown on the right side of Fig. 7. The dashed horizontal line represents the value $\hat{\chi}^2$ for which $\chi^2 < \hat{\chi}^2$ in 95% of the pseudo-experiments. The limit we find is $C_1 < 0.03$, which is an improvement with respect to what found from...
data on the LHC total cross section at the same CM energy, but still less stringent than that found from the Tevatron data for the total cross section.

Direct analysis of the Tevatron data [36] and the LHC at $\sqrt{s} = 8$ TeV [37] yield weaker limits. The effect of the coefficient $C_2$ on the cross section distributions is negligible because of the experimental uncertainties in the different intervals of $m_{t\bar{t}}$.

E. Spin correlations: LHC at $\sqrt{s} = 7$ TeV

Independent observables useful in setting further limits on the top quark structure involve spin correlation in $t\bar{t}$ events [38]. Spin correlations of pair-produced top quarks can be extracted by analysing the angular distributions of the top-quark decay products in $t \to W b$ followed by the leptonic decay of the $W$ boson $W \to l \nu$. If no acceptance cuts are applied and the spin-analysing power is effectively 100%, we have the following form of the double angular distribution [38]

$$\frac{1}{\sigma} \frac{d^2\sigma}{d \cos\theta_1 d \cos\theta_2} = \frac{1}{4}(1 + B_1 \cos\theta_1 + B_2 \cos\theta_2 - C_h \cos\theta_1 \cos\theta_2),$$

(24)

where $B_1$, $B_2$ and $C_h$ are coefficients.

Here we consider the angular distribution in the helicity basis, in which the quantization axes are taken to be the $t$ and $\bar{t}$ directions of flight in the $t\bar{t}$ zero-momentum frame. Therefore $\theta_1 (\theta_2)$ represents the angle between the direction of flight of $l^+ (l^-)$ in the $t\bar{t}$ rest frame and the $t(\bar{t})$ direction of flight in the $t\bar{t}$ zero-momentum frame. In this case the spin correlation coefficient $C_h$ is given by

$$C_h = \frac{N(\uparrow\uparrow) + N(\downarrow\downarrow) - N(\uparrow\downarrow) - N(\downarrow\uparrow)}{N(\uparrow\uparrow) + N(\downarrow\downarrow) + N(\uparrow\downarrow) + N(\downarrow\uparrow)},$$

(25)

where $N(\uparrow\uparrow) + N(\downarrow\downarrow)$ represents the number of events where the top and antitop quark spin projections are parallel, and $N(\uparrow\downarrow) + N(\downarrow\uparrow)$ is the number of events where they are anti-parallel with respect to the chosen quantization axes.

For the experimental analysis it is more convenient to use the one-dimensional distributions of the product of the cosines $O_h \equiv \cos\theta_1 \cdot \cos\theta_2$ and define an asymmetry $A_h$ which, in the absence of acceptance cuts, is determined by [38]

$$A_h = \frac{N(O_h > 0) - N(O_h < 0)}{N(O_h > 0) + N(O_h < 0)} = -\frac{C_h}{4}.$$

(26)
The most precise experimental measurement of $C_h$ at LHC is obtained by ATLAS studying at $\sqrt{s} = 7$ TeV the angular separation $\Delta\phi$ between the charged leptons in dileptonic $t\bar{t}$ events \cite{38}

$$C_{h}^{\text{meas}} = 0.37 \pm 0.06(\text{stat} + \text{syst}). \quad (27)$$

This value has to be compared with the next-to-leading order SM prediction

$$C_{h}^{\text{NLO}} = 0.31,$$  \quad (28) \]

calculated in \cite{38} including QCD and electroweak corrections to $t\bar{t}$ production and decay.

The spin correlation coefficient $C_h$ as a function of the effective operators coefficients is obtained by means of MG5, generating $10^5$ events for the process $pp \to t\bar{t} \to b\ell^+\nu\ell^-\bar{\nu}$, for different values of $C_1$ and $C_2$, and computing the asymmetry $A_h$ defined in eq. \cite{25}.

MG5 gives a tree level prediction for the total cross section $\sigma(pp \to t\bar{t} \to b\ell^+\nu\ell^-\bar{\nu})$ that we denote by $\sigma_{\text{MG5}}(C_1, C_2)$ and therefore also the derived asymmetry is a LO result that we denote it by $A_h^{\text{MG5}}(C_1, C_2)$. The tree level prediction for the asymmetry is then corrected in order to take into account the SM NLO effects by computing

$$A_h(C_1, C_2) = \frac{A_h^{\text{NLO}} \cdot \sigma^{\text{NLO}} + A_h^{\text{MG5}}(C_1, C_2) \cdot \sigma^{\text{MG5}}(C_1, C_2) - A_h^{\text{MG5}}(0, 0) \cdot \sigma^{\text{MG5}}(0, 0)}{\sigma^{\text{NLO}} + \sigma^{\text{MG5}}(C_1, C_2) - \sigma^{\text{MG5}}(0, 0)}, \quad (29)$$

where $\sigma^{\text{NLO}}$ is obtained by multiplying the NNLO theoretical cross section for $t\bar{t}$ production in \cite{17} by the leptonic decay branching ratio and $A_h^{\text{NLO}}$ is computed using eq. \cite{25} from eq. \cite{28}.

Fig. \[\text{8}\] show the limits on the coefficients $C_1$ and $C_2$ coming from the spin correlations at the LHC at $\sqrt{s} = 7$ TeV. The black line represents the correlation coefficient computed including the contributions of the operators $\hat{O}_1$ and $\hat{O}_2$ as described above. The yellow (green) bands represents the measured $C_h$ with its error at 2(1)$\sigma$ level. We can see from Fig. \[\text{8}\] that differently to $C_1$, the coefficient $C_2$ is unbounded for positive values.

F. Combined limits

The bounds on the individual coefficients $C_1$ and $C_2$ can also be computed when both operators are simultaneously present. In this case, there is an important modulation in the effect of the new operators. The combined limits coming from the data at the LHC at the two CM energies considered and those at the Tevatron are shown in Fig. \[\text{9}\]. In the same plot, also the limits coming from the spin correlations are shown.

We can see that without the data on the spin correlations the allowed region is rather large. Other analysis \cite{13,15} found a smaller region because they either kept only the leading order contribution of the operators or did not combine the limits on $C_2$ with those on $C_1$. When the full contribution of these operators is included for both of them, we need the limits from data on the spin correlations in order to exclude the larger values and obtain relevant limits.

IV. DISCUSSION

TABLE I: Limits on the coefficients $C_1$ and $C_2$ when they are varied independently of each other and simultaneously (last column). The starred numbers for LHC@14 are the expected limits.

| LHC@7   | LHC@8 | LHC@14 | combined |
|---------|-------|--------|----------|
| $-0.008 \leq C_1 \leq 0.015$ | $-0.019 \leq C_1 \leq 0.044$ | $-0.165 \leq C_1 \leq 0.025$ | $-0.135^{*} \leq C_1 \leq 0.034^{*}$ | $-0.019 \leq C_1 \leq 0.026$ |
| $-0.023 \leq C_2 \leq 0.042$ | $-0.066 \leq C_2 \leq 0.038$ | $-0.074 \leq C_2 \leq 0.029$ | $-0.023^{*} \leq C_2 \leq 0.020^{*}$ | $-0.087 \leq C_2 \leq 0.031$ |

We have collected in Table \[\text{I}\] the limits for the two coefficients $C_1$ and $C_2$ when they are varied simultaneously and independently of each other for each of the data sets. Pending results from the LHC at $\sqrt{s} = 14$ TeV, the Tevatron gives the most stringent bound on the operator $\hat{O}_1$. The LHC at $\sqrt{s} = 8$ TeV and the Tevatron give the best bounds on the operator $\hat{O}_2$. In combining the limits, all data sets are important and those from spin correlations are essential in removing large values for the coefficients $C_1$ and $C_2$ which cannot be ruled out by the total cross section data because of cancellations between the two contributions.
FIG. 9: Combined limits on the coefficients $C_1$ and $C_2$ from data at the LHC ($\sqrt{s} = 8$ and 7 TeV) and Tevatron ($\sqrt{s} = 1.96$ TeV). Values in the regions, respectively, in hatched blue and hatched red from LHC, yellow from Tevatron and gray from spin correlations at the LHC are excluded at 95% CL. The allowed region corresponds to the white area. On the right a zoomed plot around the allowed values.

A. The size of the top quark

Deviations from the point-like behavior of a particle are usually expressed in terms of charge radius and anomalous magnetic moment. These quantities have been defined in eq. (3) and eq. (4). In the case of the top quark the dominant probe is charged under the $SU(3)$ group of strong interactions. Since there is no definite boundary, the size is usually discussed in terms of root mean squared (RMS) radius.

We should first identify the size that comes from radiative corrections. This part is a departure from the point-like behavior due to the cloud of virtual states surrounding any particle in quantum field theory. For the top quark, the leading radiative contribution to the squared mean radius can be computed in perturbation theory to one-loop order in QCD and it is in general of order $(\alpha_s/2\pi)^1/m_t^2$. Accordingly, this contribution to the the RMS radius is about $10^{-5}$ fm. EW interactions give an additional (smaller) contribution which can be neglected.

We can obtain an estimate of the fraction of the radius and moment of the composite top quark which is not part of the radiative corrections in terms of the effective operator coefficients. Using the formulas in eq. (7) to compute the form factors of eq. (2), we have that, using eq. (9),

$$\langle \vec{r}^2 \rangle = \frac{6}{4} \frac{4m_t C_1 + 2 \nu C_2}{m_t^4} \quad \text{and} \quad \mu = 1 + 2 \frac{\nu}{m_t} C_2,$$

with $2\nu C_2/m_t$ equal to the anomalous component of the magnetic moment. The best constrains on the coefficients $C_1$ and $C_2$ when taken independently

$$-0.008 \leq C_1 \leq 0.015 \quad \text{and} \quad -0.023 \leq C_2 \leq 0.020$$

(31)

correspond to a RMS radius

$$\sqrt{\langle \vec{r}^2 \rangle} < 4.6 \times 10^{-4} \text{ fm} \quad (95\% \text{ CL}),$$

(32)

and an anomalous magnetic moment

$$-0.046 < \mu - 1 < 0.040 \quad (95\% \text{ CL}).$$

(33)
A similar bound on the anomalous magnetic moment of the top quark has been reported in [12]. The bounds found in [14] are weaker. At the time of writing this paper, an apparently stronger bound was found in [13] which however agrees with our limit if taken at the 68% CL.

These limits become weaker if the constraints are taken simultaneously for the two operators:

\[ \sqrt{\langle r^2 \rangle} < 7.4 \times 10^{-4} \text{ fm} \quad \text{and} \quad -0.17 < \mu - 1 < 0.062 \quad (95\% \text{ CL}) \]

To put the above limits in perspective, let us consider the proton and the electron as the best known examples of, respectively, a composite and (presumably) point-like particle.

The radiative part of the proton RMS radius is about $10^{-2}$ fm. Its actual size, as measured in electron-proton elastic scattering experiments, is much larger: it is about 0.9 fm [40]. The factor of 100 in the ratio of these two numbers is not far from what we have found in the case of the top quark.

The electron, which is believed to be a point-like particle, has a limit on its RMS which does not originate in radiative corrections that is not far from that in eq. (32) for the top quark: it is $10^{-5}$ fm [41]. In other words, the top quark does not seem to deviate from a point-like object down to a scale close to that of the electron. Notice that the bound in the electron case comes from an analysis of $e^+e^- \rightarrow e^+e^-$ while in our case that for the top quark comes from $\bar{q}q \rightarrow \bar{t}t$ rather than the more direct $t \bar{t} \rightarrow t \bar{t}$ which would be probed by the process with four top-quarks in the final states. The limit on the part of the electron anomalous magnetic moment not accounted for by radiative corrections is very strong—because of its interaction with a classical magnetic field—and equal to $10^{-12}$ [42].

B. Compositeness and physics beyond the SM

The most direct way to associate some compositeness scales $\Lambda_1$ and $\Lambda_2$ to the effect of the operators in eq. (6) is through the identification

\[ \frac{1}{\Lambda_1} = \frac{g_1|C_1|}{m_t^2} \quad \text{and} \quad \frac{1}{\Lambda_2} = \frac{g_2|C_2|}{2m_t^2}. \]

(35)

The identification of $\Lambda_2$ in eq. (35) is based on the full EW symmetry group for which the operator $\hat{O}_2$ must be considered of dimension 6. In this way, it is simple to translate the bounds on $C_1$ and $C_2$, obtained in the previous section, into limits on these two scales of compositeness. We have that

\[ \Lambda_1 > \begin{cases} 1.3 \text{ TeV (Tevatron)} & \text{if} \quad C_1 > 0 \\ 0.4 \text{ TeV (LHC@7)} & \text{if} \quad C_1 < 0 \end{cases} \quad \text{and} \quad \Lambda_2 > \begin{cases} 1.1 \text{ TeV (Tevatron)} & \text{if} \quad C_2 > 0 \\ 0.9 \text{ TeV (LHC@7)} & \text{if} \quad C_2 < 0 \end{cases} \quad (95\% \text{ CL}), \]

(36)

These results can be compared with bounds coming from EW precision measurements [43]: the scale of the four-fermion operators (for light quarks) is bounded to values higher, depending on the sign and the procedure, than 6.6 or 9.5 TeV. More generally, by using various other operators an overall bound of $\Lambda > 17$ TeV is found.

While the above identification of the compositeness scale is straightforward—it plays the role of expansion parameter for the operators—its link to specific models is more indirect.

In the following sections we discuss how to translate bounds on $C_1$ and $C_2$ into limits on the parameters of two models of physics beyond the SM. In doing so, we must bear in mind that often numerical values, when used within a given model, are more orders of magnitude than precise numbers because both naive power counting and the QCD analogy may not be correct in a generic strongly interacting theory.

1. Contact interactions

Contact interactions are usually introduced to parametrize generic models of compositeness [44]. These have been traditionally described by the interaction

\[ \frac{2\pi}{\Lambda_{CI}^2} \bar{\psi}_L \gamma^\mu \psi_L \bar{\psi}_L \gamma_\mu \psi_L, \]

(37)

where $\psi = (u \ d)^T$ and $\Lambda_{CI}$ is identified as the contact interaction scale. The factor of $2\pi$ is conventional and suggested by a strongly interacting sector, the coupling of which is assumed to be $g^2 \simeq 2\pi$. Under such an assumption, the
effective four-fermion operator can be thought as generated by the exchange of a heavy resonance, which couples to the fermion with strength $g$, and that has been integrated out. The effect of four-fermion operators with light quarks in $\sigma(pp \to jj + X)$ was first discussed in [44] and more recently in [45, 46].

Performing a field redefinition, using the equations of motion for the gluon field, it is possible to rewrite the operator $\hat{O}_1$ as a combination of four-fermion interaction terms:

$$\hat{O}_1 = \frac{g^2 C_1}{m_t^2} t_{\gamma\mu} T_A \sum_q \bar{q} \gamma^\mu T^A q.$$  

where the summation runs over all quark species. Assuming contact interactions which are flavor universal, we can directly relate the contribution of the operator $\hat{O}_1$ to that in eq. (37). By taking into account color factors, flavor and chirality multiplicity, we have the following identification:

$$\Lambda_{CI} = \sqrt{\frac{6\pi}{g^2 C_1 m_t^2}}.$$  

The constraints on the coefficients $C_1$ therefore applies to this scale and gives

$$\Lambda_{CI} > \begin{cases} 
5.0 \text{ TeV} & (\text{Tevatron}) \\
1.4 \text{ TeV} & (\text{LHC@7}) \\
1.5 \text{ TeV} & (\text{LHC@8})
\end{cases} \quad (95\% \text{ CL}),$$  

respectively.

For recent bounds on the characteristic scale of these operators from measurements of dijets at the LHC, see [47]. In these references, $\Lambda_{CI}$ in eq. (37) is found to be around 10 TeV in the case of light quarks. The limits (40) coming from the top quark are less stringent but of the same order of magnitude.

2. Strongly interacting light Higgs models

Strongly interacting light Higgs model (SILH) are theories in which the Higgs multiplet is assumed to belong to a new (strong) sector responsible for the EW symmetry breaking [9]. These models are broadly characterized by two parameters, a coupling constant $g^*$ and a scale $m^*$, which denotes the mass of the heavy physical states.

The leading new physics effects are parametrized in terms of dimension-6 operators, involving the Higgs and the other SM fields, consistent with $SU(3)_C \times SU(2)_L \times U(1)_Y$ symmetry. Among these operators, we are interested in the following one

$$c_{tG} \bar{q}_L H^c \sigma^{\mu\nu} T_A t_R G^A_{\mu\nu} + \text{h.c.},$$  

where $q^T = (t \ b)$ and $H^c = i\sigma^2 H^*$ is the conjugated Higgs field. The size of the coefficients of these effective operators is usually derived by naive dimensional analysis (NDA) [18] as described in [9] [19].

Naive estimation of the coefficient $c_{tG}$ in eq. (41) gives $c_{tG} \sim g_t y_t/m_t^2$. After EW symmetry breaking, the operator in eq. (41) reduces to the operator $\hat{O}_2$ of eq. (6) with the identification

$$|C_2|/2m_t^2 = y_t/m_*^2.$$  

In this way we can translate the bounds on $C_2$ into limits on the mass $m_*$. By using the results of the previous section we find

$$m_* > \begin{cases} 
1.2 \text{ TeV} & (\text{Tevatron}) \\
0.9 \text{ TeV} & (\text{LHC@7}) \\
0.9 \text{ TeV} & (\text{LHC@8})
\end{cases} \quad (95\% \text{ CL}).$$  

A special phenomenological realization of SILH is represented by theories where the Higgs doublet is a composite Goldstone boson of a spontaneously-broken symmetry of the strong dynamics [11, 2]. In these models the ratio $m_*/g_* \equiv f$ is identified with the decay constant of the Goldstone boson associated with the symmetry breaking. An important quantity of these composite models is the ratio $\xi = v^2/f^2$, which characterizes the distance between the EW and the strong dynamics scales.
How the scale $m_\ast$ should properly interpreted within the composite models depends on whether the assumption of minimal coupling is taken as a guiding principle or not. For a recent discussion and criticism about this point see \cite{49}.

If we assume the strongly interacting theory to be minimally coupled, the coupling of the composite top quark to the gluon field remains the same as for the SM fermions. Accordingly, the operator in eq. (11) can be generated only at loop level—by means of the coupling to the heavier resonances—and the coefficient $c_{tG}$ receives a further suppression by a factor of $g^2/16\pi^2$. In this case, while it is possible to obtain a bound on the scale $f$—because of the identification $|C_2|/2m_t^2 = yr/16\pi^2 f^2$—and therefore on the parameter $\xi$, the constraints we have found are too weak to bound the parameter space of these models.

On the other hand, if the interaction with the gluon field of the composite top quark is assumed to be non-minimal, which is the most reasonable assumption for a composite object, then we can start out directly with the interaction vertexes in eq. (1) and $m_\ast$ can be taken to coincide with the mass of the heavy composite fermion. The result holds both in the case of complete and partial compositeness. A specific model of partial compositeness in which this scenario is realized is discussed in the Appendix A.

In composite models, both the right-handed and left-handed top quark should have a sizable degree of compositeness. The right-handed top quark $t_R$ could be completely composed, there are no experimental limits beside those discussed here. The compositeness of the left-handed top quark $t_L$ is more constrained because of its pairing with the $b$ quarks in a $SU(2)$ doublet and the experimental constraints from the decay $Z \to bb$. However, it is possible to show \cite{50} how to protect $b_L$ from corrections in such a decay thus leaving open the possibility of its being a composite state as well.

In the case of the composite Higgs models, the composite fermion masses must be close to the scale $f$ \cite{10,51} in order for the Higgs boson mass to be equal to its experimental value. If we assume a non-minimal coupling scenario, following the discussion above, it is possible to identify $m_\ast \simeq f$ in eq. (42). In this case the parameter $\xi$ is accordingly constrained to be

$$\xi < \begin{cases} 
0.04 \text{ (Tevatron)} \\
0.07 \text{ (LHC@7)} \\
0.08 \text{ (LHC@8)} \end{cases} \quad \text{(95\% CL).} \quad \text{(44)}$$

Notice that values of $\xi$ below 0.1 requires a high degree of cancellation between different terms in order to keep the Higgs boson mass at its experimental value and are therefore considered unnatural and make the usefulness of the model doubtful.

In considering the above constraints, we must bear in mind that there are many caveats depending on the connection in a specific model between the composite states and the top quark. Most notably, in models with partial compositeness further suppression factors—making the above limits weaker—may come from the mixing angles between heavy composite and light states, as shown in a specific model in the Appendix A. The same model also shows that while the limits in eq. (44) can be slightly relaxed, they cannot be made substantially weaker.

An independent limit on the scale $f$ can be obtained by means of the operator $\hat{O}_1$, which, using the equations of motion, gives rise to the four-fermion operator of eq. (38). This operator, according to NDA and minimal coupling, has a coefficient that is proportional to $f^{-2}$ without any loop suppression. An example is given by the typical four-fermion operator considered in SILH theories that involves only right handed top quarks:

$$c_{4t} \bar{t}_R \gamma^\mu t_R \bar{t}_R \gamma^\nu t_R.$$ \quad \text{(45)}

A naive estimation of the coefficient $c_{4t}$ gives $c_{4t} \sim g_2^2/f^2$. A comparison of this operator with the one in eq. (38), after taking into account the color factors, gives the following identification:

$$|C_1|/3m_t^2 = 1/f^2.$$ \quad \text{(46)}

In this way, we could directly translate the constraints on the coefficient $C_1$ into limits on the scale $f$ and the parameter $\xi$ which are comparable to those in eq. (44). However, this is only possible if we treat all flavors on an equal footing, an assumption that does not apply to most composite models where the coupling to the light quarks are explicitly taken to be different and much suppressed with respect to that to the top quark.

Finally, the limits on $m_\ast$ in eq. (43) imply that the masses of these fermion are close or larger than 1 TeV. These states are described as custodial fermions because they prevent the mass of the Higgs boson from being too large but this is only true if their masses are less than 1 TeV \cite{10,51}.

Appendix A: Partial compositeness and non-minimal coupling

In this appendix we introduce an explicit model of partial compositeness to show how the operators in eq. [6] cannot be rotated away at the tree level by a field redefinition if we assume non-minimal coupling. In the process, we also obtain an estimate of the additional suppression generated by the mixing between composite and SM fermions.

Many realizations of composite Higgs models rely on the hypothesis of partial compositeness [4], in which each SM state has a composite partner with equal quantum numbers under the SM symmetries. These fields are multiples of elementary fields as in the following lagrangian:

\[ \Psi = \left( T \ X_{5/3} \right)_T \]

(A1)

contains a doublet \( Q = (T \ B)^T \) with the same quantum numbers of the SM left-handed doublet \( q^d_L = (t^d_L \ b^d_L)^T \), while \( T \) has the same quantum numbers of the SM right-handed top \( t^d_R \).

The composite fermion states have an explicit Dirac mass term and are assumed to mix linearly with the SM elementary fields as in the following lagrangian:

\[
\mathcal{L}_{\text{mass}} + \mathcal{L}_{\text{mix}} = -M_Q \text{Tr} \Psi \bar{\Psi} - M_T \bar{T} T - \Delta_Q \bar{Q} R q^d_L - \Delta_T \bar{T} L t^d_L + \text{h.c.} \\
= -\bar{T} R (M_Q T L + \Delta_Q q^d_L) - \bar{T} L (M_T \bar{T} R + \Delta_T t^d_L) + \text{h.c.} + \ldots
\]

(A2)

The mass mixing arising from \( \mathcal{L}_{\text{mix}} \) can be diagonalized by the following field transformations:

\[
\begin{align*}
& t^d_L = \cos \varphi_L t_L + \sin \varphi_L T_L \\
& T_L = -\sin \varphi_L t_L + \cos \varphi_L T_L
\end{align*}
\]

and

\[
\begin{align*}
& t^d_R = \cos \varphi_R t_L + \sin \varphi_R T_L \\
& \bar{T} R = -\sin \varphi_R t_L + \cos \varphi_R T_L.
\end{align*}
\]

(A3)

The top fields \( t_L \) and \( t_R \) are the massless (before EW symmetry breaking) partially-composite eigenstates, while \( T_L \) and \( T_R \) are the massive composite ones, their masses being \( M_T = M_Q \cos \varphi_L + \Delta_Q \sin \varphi_L \) and \( M_T = M_T \cos \varphi_R + \Delta_T \sin \varphi_R \). The mixing angles \( \varphi_L \) and \( \varphi_R \) are defined such that \( \tan \varphi_L = \Delta_Q/M_Q \) and \( \tan \varphi_R = \Delta_T/M_T \).

QCD gauge fields are coupled to the fermions through the covariant derivative \( \bar{\Psi} = \gamma^\mu \left( \partial_\mu - ig_s T_A G_\mu^a \right) \) in the kinetic terms:

\[
\mathcal{L}_{\text{kin}} = -\bar{q}^d_L i \bar{\Psi} q^d_L + i \bar{t}^d_L i \bar{\Psi} t^d_L + \bar{T} i \bar{\Psi} T + \bar{\bar{T}} i \bar{\Psi} \bar{T} + \ldots
\]

(A4)

EW interactions are not relevant for our discussion and they are explicitly set to zero. Once the rotation of the fields into the mass eigenstates is performed, using eq. (A3), the lagrangian reads:

\[
\mathcal{L}_{\text{kin}} + \mathcal{L}_{\text{mass}} + \mathcal{L}_{\text{mix}} = \bar{t}^d_L \gamma^\mu \partial_\mu t^d_L + \bar{t}^d_R \gamma^\mu \partial_\mu t^d_R + \bar{T} \gamma^\mu \partial_\mu T + \bar{\bar{T}} \gamma^\mu \partial_\mu \bar{T} \\
- M_T (\bar{T} R t^d_L + \text{h.c.}) - M_T (\bar{T} R t^d_R + \text{h.c.}) + \ldots
\]

(A5)

If the composite sector is assumed to be minimally coupled then the chromo-magnetic operator in eq. [41] can only be generated at loop level (for an explicit example see Appendix A of [52]). The same holds for the other operator in eq. [4].

On the other hand, if we allow the composite sector to be non-minimally coupled, then it is possible to introduce the following chromo-magnetic interaction term among the composite fermions:

\[
\mathcal{L}' = \kappa \bar{Q} H^c \sigma^{\mu\nu} G_{\mu\nu} T + \text{h.c.},
\]

(A6)

where \( H^c \) is the conjugated composite Higgs field. This operator is suppressed by two inverse powers of the composite fermion mass, namely the coefficient \( \kappa \) can be taken to be \( \kappa \sim g_y y_t / M_Q^2 \), where \( y_t \) is the Yukawa coupling of the top quark. After EW symmetry breaking, by performing the rotation eq. (A3), we obtain

\[
\mathcal{L}' = \sin \varphi_L \sin \varphi_R \frac{g_y y_t}{M_Q} \bar{t}^d_L \sigma^{\mu\nu} G_{\mu\nu} t^d_R + \text{h.c.} + \ldots
\]

(A7)
where the dots stand for other terms which involve the heavy composite fields. A similar argument could be made for the other operator in eq. (6).

Comparing eq. (A7) with eq. (42), we have the following identification:

\[ m^2 = M_Q^2 / \sin \varphi_L \sin \varphi_R. \]  

(A8)

Eq. (A8) shows that limits on \( M_Q \) turn out to be weaker than those on \( m^* \) because of the presence of the suppression factor given by the sine of the mixing angles. However, these mixing angles cannot be too small because they enter into the definition of the top Yukawa coupling, which is generated from the following interaction:

\[ \mathcal{L}_{Yuk} = Y^* \bar{Q} H^* \tilde{T} + \text{h.c.}. \]  

(A9)

Using eq. (A3), one finds that the top Yukawa coupling is given by

\[ y_t = \sin \varphi_L Y^* \sin \varphi_R. \]  

(A10)

Perturbative control on the strength of the composite interaction requires that \( Y^* \ll 3 \). Then, in order to have \( y_t \sim 1 \), one needs sizeable mixing angles \( \varphi_L \) and \( \varphi_R \).
