Abstract. Motivated by the string gas cosmological model, which predicts a blue tilt of the primordial gravitational wave spectrum, we examine the constraints imposed by current and planned observations on a blue tilted tensor spectrum. Starting from an expression for the primordial gravitational wave spectrum normalized using cosmic microwave background observations, pulsar timing, direct detection and nucleosynthesis bounds are examined. If we assume a tensor-to-scalar ratio on scales of the cosmic microwave background which equals the current observational upper bound, we obtain from these current observations constraints on the tensor spectral index of $n_T \lesssim 0.79$, $n_T \lesssim 0.53$, and $n_T \lesssim 0.15$ respectively.

Keywords: gravity waves/theory, string theory and cosmology, cosmology of theories beyond the SM, physics of the early universe

ArXiv ePrint: 0711.4602
A stochastic background of primordial gravitational waves represents valuable information about the very early universe as well as a way to discriminate between the myriad cosmological models currently proposed. Although a stochastic background of gravitational waves has yet to be directly detected, efforts are being made to do so by many current and future experiments, some of the largest being LIGO, GEO600, TAMA, and LISA [1]. A stochastic background of gravitational waves is characterized by the gravitational wave spectrum

$$\Omega_{gw} = \frac{1}{\rho_c} \frac{d\rho_{gw}}{d \ln f},$$

where $\rho_c$ is the critical density of the universe, $\rho_{gw}$ is the energy density of the background gravitational waves and $f$ is frequency [1]. In the above, the energy density in gravitational waves is written as an integral over $\ln f$, and the derivative picks out the integrand. In practice, the gravitational wave spectrum is commonly assumed to depend on frequency as a power of $f$.

Within the framework of the inflationary universe scenario the primordial gravitational wave spectrum is predicted to be nearly scale invariant with a slight red tilt [2], i.e. more power at large scales. The reason for the red tilt is that the amplitude of the gravitational wave spectrum on a fixed scale $k$ is set by the Hubble constant $H$ at the time $t_i(k)$ when the scale $k$ exits the Hubble radius during the period of inflation. Smaller scales exit the Hubble radius later when the Hubble constant is smaller, leading to the red tilt. However, there do exist cosmological models alternative to the standard inflationary scenario which predict a blue tilt of the gravitational wave spectrum, i.e. more power at small scales, which have not yet been ruled out by observations. One cosmological model that predicts such a tilt is string gas cosmology [3].
String gas cosmology [3] is an approach to string cosmology which starts from the new degrees of freedom and symmetries which string theory contains, but particle physics-based models lack, namely string winding modes, string oscillatory modes and T-duality symmetry, and uses them to develop a new cosmological model. The claim is that by making these crucial stringy additions, one obtains a new cosmological model which is singularity free [3], generates nearly scale-invariant scalar metric perturbations from initial string thermodynamic fluctuations [4,5] and provides a natural explanation for the observed dimensionality of space [3] (see [6] for an overview of the string gas cosmology structure formation scenario). A key result which emerges [7] from string gas cosmology is that the gravitational wave spectrum has a slight blue tilt, giving rise to a testable prediction different from that of the inflationary universe paradigm.

Using string gas cosmology as a motivation, in this work we will focus on how a tensor spectrum with a blue tilt can be constrained by current observational results, and what the prospects for improved constraints from some planned experiments are.

The starting point of our analysis will be an expression for the primordial gravitational wave spectrum normalized by cosmic microwave background (CMB) observations. Chongchitnan and Efstathiou [8] have derived just such an expression with a pivot scale \( k_0 = 0.002 \) Mpc\(^{-1}\) using the combined results from multiple surveys. Using the value \( P_S(k_0) \simeq 2.21 \times 10^{-9} \) for the amplitude of the scalar power spectrum evaluated at the pivot scale, they found that \( \Omega_{gw}(f) \) can be written as

\[
h^2 \Omega_{gw}(f) \simeq 4.36 \times 10^{-15}r \left( \frac{f}{f_0} \right)^{n_T},
\]

where \( f_0 = 3.10 \times 10^{-18} \) Hz. Solving this result for the tilt of the gravitational wave spectrum, \( n_T \), we get the explicit expression

\[
n_T \simeq \frac{1}{\ln(f) - \ln(f_0)} \ln \left( 2.29 \times 10^{14} \frac{h^2 \Omega_{gw}(f)}{r} \right).
\]

In the above equations \( r \) is the tensor-to-scalar ratio evaluated at the pivot scale,

\[
r = \frac{P_T(k_0)}{P_S(k_0)}.
\]

The calculation of the tensor-to-scalar ratio depends quite sensitively on the parameters of the cosmological model under consideration. For that reason we choose to leave \( r \) as a free parameter in the main expressions calculated in this work. However, for the sake of examining some numerical values of the constraints derived here we will insert a value of \( r \) corresponding to the current upper bound into our results. Note, however, that the bounds we derive depend only logarithmically on \( r \). In each case we choose to use the value of the tensor-to-scalar ratio given by the combined three-year Wilkinson Microwave Anisotropy Probe (WMAP) and lensing normalized Sloan Digital Sky Survey (SDSS) data applied to a typical ΛCDM model including tensors [2].

In sections 2 and 3 we will use the expression for the tilt of the gravitational wave spectrum (3) along with several direct detection constraints to calculate the bounds on the required blue tilt of the spectrum. In section 4 we calculate the bound on the required blue tilt of the spectrum arising indirectly from the theory of big-bang nucleosynthesis. In section 5 we will investigate whether the CMB observations are compatible with the calculated bounds, or whether they will offer even tighter constraints. We conclude with a discussion of our findings along with other issues related to the method used.
2. Pulsar timing

High precision measurements of millisecond pulsars provide a natural way to study low frequency gravitational waves. A gravitational wave passing between the Earth and the pulsar will cause a slight change in the time of arrival of the pulse leading to a detectable signal.

2.1. Parkes pulsar timing array

The Parkes pulsar timing array (PPTA) project [10] is a pulsar timing experiment using the Parkes 64 m radio telescope located in Australia with the ultimate goal of reaching the required sensitivity to make a direct detection of gravitational waves. The PPTA project hopes to make timing observations of a sample of twenty millisecond pulsars, ten or more of them with a precision of less than approximately 100 ns.

Jenet et al [11] have developed a technique to make a definitive detection of a stochastic gravitational wave background by looking for correlations between pulsar observations. They have applied their method to data from seven pulsars observed by the PPTA project combined with an earlier data set to find a constraint on the amplitude of the characteristic strain spectrum. They then used this result to place a bound on the primordial gravitational wave spectrum [12]

\[ h^2\Omega_{gw}(1/8\text{ yr}) \leq 2.0 \times 10^{-8}. \]

(5)

Plugging the constraint of Jenet et al into equation (3) at the frequency \( f = 1/8\text{ yr} \approx 3.96 \times 10^{-9} \text{ Hz} \) we obtain a constraint

\[ n_T \lesssim 0.0477 \ln \left( \frac{4.59 \times 10^6}{r} \right). \]

(6)

The WMAP + SDSS data places a bound \( r < 0.30 \) on the tensor-to-scalar ratio [2]. Inserting \( r = 0.30 \) into the above equation we find that the current pulsar timing observations constrain the blue tilt of the tensor spectrum to \( n_T \lesssim 0.79 \).

Jenet et al have also used simulated data to determine the upper bound on the primordial gravitational wave spectrum expected from future pulsar observations. Using a simulated data set of twenty pulsars timed with an rms timing residual of 100 ns over five years they calculated [12]

\[ h^2\Omega_{gw}(1/8\text{ yr}) \leq 9.1 \times 10^{-11}. \]

(7)

Plugging this improved constraint into equation (3) at the frequency \( f = 1/8\text{ yr} \) we get a bound

\[ n_T \lesssim 0.0477 \ln \left( \frac{2.09 \times 10^4}{r} \right), \]

(8)

and again using the value \( r = 0.30 \), we find that, in the absence of a detection, future pulsar timing observations could tighten the constraint on the blue tilt to \( n_T \lesssim 0.53 \).
3. Interferometers

Interferometer experiments offer a way to directly measure the gravitational wave strain spectrum with many observatories currently running or planned for the future. Interferometers in different locations form a network that will search for a correlated signal between detectors beneath uncorrelated detector noise, in order to improve sensitivity.

3.1. LIGO

The Laser Interferometer Gravitational Wave Observatory (LIGO) [13] is a ground-based interferometer project operating in the frequency range of 10 Hz—a few kilohertz. LIGO consists of two collocated Michelson interferometers in Hanford, Washington, H1 with 4 km long arms, and H2 with 2 km long arms, along with a third interferometer in Livingston Parish, Louisiana, L1 with 4 km long arms.

Most recently LIGO has performed its fourth science run, S4, with improved interferometer sensitivity. Abbott et al [13] have used the S4 data to calculate a limit on the amplitude of a frequency independent gravitational wave spectrum. They found a bound

$$\Omega_{gw} < 6.5 \times 10^{-5}$$

in the frequency range 51–150 Hz. Inserting this value into equation (3) at the frequency $f = 100$ Hz we get a constraint

$$n_T \lesssim 0.0223 \ln \left( \frac{1.49 \times 10^{10}h^2}{r} \right).$$

The WMAP + SDSS data also provide a value of $h = 0.716$ for the Hubble parameter [9]. Inserting this along with $r = 0.30$ into the above bound, we find that the current LIGO results place a constraint $n_T \lesssim 0.53$ on the blue tilt of the tensor spectrum.

The final phase of LIGO, named Advanced LIGO, hopes to reach a detection sensitivity of [13]

$$\Omega_{gw} \sim 10^{-9}. $$

Plugging this value into equation (3) at $f = 100$ Hz, we find that if Advanced LIGO does not make a positive detection of a gravitational wave background then it will place a bound on the blue tilt of the tensor spectrum

$$n_T \lesssim 0.0223 \ln \left( \frac{2.29 \times 10^{5}h^2}{r} \right).$$

Using $r = 0.30$ and $h = 0.716$ in this expression, Advanced LIGO would then constrain the blue tilt of the tensor spectrum to $n_T \lesssim 0.29$. 

3.2. LISA

The Laser Interferometer Space Antenna (LISA) [14] is a planned space-based interferometer experiment operating in the megahertz range. LISA will consist of three drag-free spacecraft each at the corner of an equilateral triangle with sides of length $5 \times 10^9$ m. Each spacecraft has two optical assemblies pointed towards the other two spacecraft forming three Michelson interferometers. This triangle formation will orbit the sun in an Earth-like orbit separated from us by approximately fifty million kilometers. The goal of LISA is to reach a sensitivity of

$$h^2 \Omega_{\text{gw}}(1 \text{ mHz}) \simeq 1 \times 10^{-12}.$$  (13)

At the LISA sensitivity level one would expect gravitational wave signals from supermassive black hole binaries, other binary systems and super-massive black hole formation to be present. Assuming these predicted signals could somehow be removed and LISA does not detect any primordial signal, we can plug this predicted limit into equation (3) at $f = 1 \text{ mHz}$ to obtain a limit on the blue tilt of the primordial gravitational wave spectrum

$$n_T \lesssim 0.0299 \ln \left( \frac{2.29 \times 10^2}{r} \right).$$  (14)

Inserting $r = 0.30$ into this equation we find that LISA could potentially place a constraint $n_T \lesssim 0.20$ on the blue tilt.

4. Nucleosynthesis

The theory of big-bang nucleosynthesis (BBN) successfully predicts the observed abundances of several light elements in the universe. In doing so, BBN places constraints on a number of cosmological parameters. This in turn results in an indirect constraint on the energy density in a gravitational wave background as follows: the presence of a significant amount of gravitational radiation at the time of nucleosynthesis will change the total energy density of the universe, which affects the rate of expansion in that era, leading to an overabundance of helium and thus spoiling the predictions of BBN [1]. Assuming $N_\nu = 4.4$, where $N_\nu$ is the effective number of neutrino species at the time of nucleosynthesis, the BBN bound is

$$\int_{f_1}^{f_2} \Omega_{\text{gw}}(f) \, d(\ln f) < 1.5 \times 10^{-5}.$$  (15)

Plugging equation (2) into the left-hand side and performing the integration we obtain the inequality

$$\frac{f_2^{n_T} - f_1^{n_T}}{n_T} < 3.4 \times 10^9 \frac{h^2 f_0^{n_T}}{r}.$$  (16)

In order to apply the above result, we must discuss the two integration limits $f_1$ and $f_2$. The lower cutoff frequency $f_1$ corresponds to the Hubble radius at the time of BBN and takes the value $f_1 \sim 10^{-10}$ Hz. For wavelengths larger than the Hubble radius, the gravitational waves are frozen out [16] (see e.g. [17] for a review) and thus do not act like radiation. The upper cutoff frequency $f_2$ is the ultraviolet cutoff. We will take it to be...
given by the Planck frequency, i.e. \( f_2 = f_{\text{Pl}} = 1.86 \times 10^{43} \) Hz. Substituting these two limits into equation (16) along with the WMAP + SDSS values \( r = 0.30 \) and \( h = 0.716 \) then solving numerically for \( n_T \), we find the bound on the blue tilt of the tensor spectrum from BBN to be

\[
n_T \lesssim 0.15. \tag{17}
\]

Had we instead inserted for \( f_2 \) the scale of grand unification, \( 10^{16} \) GeV, or the Hubble rate during a simple large field inflation model, which is \( 10^{13} \) GeV, the bound would be slightly relaxed to 0.16 or 0.17, respectively. Thus, the dependence of the bound on the uncertain ultraviolet cutoff scale \( f_2 \) is quite mild.

Lastly, we do not want \( \Omega_{\text{gw}} > 1 \) at any scale within the integration bounds. Since we are working with such large frequencies we should check to be sure that this condition is satisfied. Substituting the value of the tensor spectral index determined by BBN back into equation (2) we find that \( \Omega_{\text{gw}}(f_{\text{Pl}}) = 3.93 \times 10^{-6} \), meaning that our requirement is indeed satisfied for all frequencies within the interval of integration.

5. Cosmic microwave background

Observations of the CMB have implications for a wide variety of topics including constraining inflation, dark matter and large-scale structure. The mission of WMAP is to produce full-sky maps of the CMB anisotropy and the recently published three-year results are an improvement upon previous observations. A reduction in instrument noise produced spectra which are three times more sensitive in the noise limited region, independent years of data allow for cross-checks, the instrument calibration and response have been better characterized and a thorough analysis of the polarization data has improved the understanding of the data [18]. Using three-year WMAP data, the derived angular power spectrum of the temperature anisotropy, \( C_{l}^{TT} \), where \( l \) is the multipole moment, is cosmic variance limited to \( l = 400 \) and the signal to noise ratio exceeds unity to \( l = 1000 \) [18]. This high precision cosmological data set provides another method of placing constraints on the value of the tensor spectral index.

Using the code for anisotropies in the microwave background (CAMB) [19] we can simulate how a blue tilt of the primordial gravitational wave background would effect the anisotropies in the CMB. To examine possible constraints we employ the following method: first, we calculate \( C_{l}^{TT} \) using CAMB for each of the three current bounds on \( n_T \) calculated in the previous sections; second, we calculate \( C_{l}^{TT} \) using CAMB, this time with a standard inflationary relation: \( n_T = -r/8 \) [2]; finally, we compare the output \( C_{l}^{TT} \) data for the models with a blue tilt against the output for the model with the ‘usual’ value of the tensor spectral index (the above relation from inflationary cosmology). For consistency with the previous sections, when running CAMB we choose our input cosmological parameters to be those calculated using the WMAP + SDSS data for a \( \Lambda \)CDM model with tensors [9].

From figure 1 we can clearly see that the power spectrum of the temperature anisotropy for models with a blue tensor spectral index does not vary much from that calculated using a standard inflationary definition of the tensor spectral index. In fact, the difference is within the cosmic variance error at all \( l \leq 1000 \) for each of the three bounds calculated using the PPTA observations, LIGO observations and the theory of BBN. Thus, we find that the cosmic microwave background does not offer any constraints on the blue tilt of the gravitational wave spectrum tighter than those already calculated.
Observational constraints on theories with a blue spectrum of tensor modes

Figure 1. Magnitude of the difference between the TT power spectrum for a model with a blue tensor spectral index and the TT power spectrum for a model with a tensor spectral index defined as: $n_T = -r/8$. Shown here are the cases $n_T = 0.15$ (green), $n_T = 0.53$ (yellow) and $n_T = 0.79$ (orange) respectively. The dashed line represents the cosmic variance error at each $l$.

6. Conclusions

A stochastic background of primordial gravitational waves is a prediction of many cosmological models. Assuming the gravitational wave spectrum depends as a power on frequency, then this spectrum can be characterized by its tilt and amplitude. Most models predict the tilt to be nearly scale invariant but slightly red, while some models, like string gas cosmology, predict a slight blue tilt. Although a gravitational wave background has yet to be directly detected, observational results can already be used to constrain it.

Using the current results from pulsar timing observations, direct detection observations and the theory of nucleosynthesis, we have placed bounds on the possible blue tilt of the gravitational wave background. After completion of this work we became aware of [20] in which a master equation was derived which relates the short wavelength observable $\Omega_{gw}(f)$ to the tensor-to-scalar ratio measured with the CMB. The goal of that work was to develop a formulation which is as general as possible. In particular, the equation of state parameter and the tensor spectral index are taken to be arbitrary functions of the scale factor and wavenumber respectively, not constants as is often assumed. Their master equation is thus a more general version of our ‘master’ equation (2) and we could have just as easily used it as our starting point. In fact, we have confirmed that by choosing a constant value $w = 1/3$ for the equation of state parameter (which is described as the most logical value in [20]) and numerical values for other cosmological parameters that match our choices above, we can indeed re-derive all of our results from the master equation of [20]. We consider this a good consistency check for the constraints derived in this work. The authors of [20] do include a discussion of some of the same types of observations mentioned here, namely laser interferometer and pulsar timing; however,
we stress that they do not use the current numerical constraint from any particular observatories to compute actual upper bounds on $n_T$, which was the purpose of this work. The authors of [20] also discuss a constraint on $n_T$ coming from BBN, but they take the constraint on $\Omega_{gw}$ from BBN to be a constant across all frequencies rather than integrating their master equation as was done in this work. In the end they find a bound on the tilt, $n_T \lesssim 0.36$, weaker than the one obtained here.

By far the tightest constraint on the tilt comes from big-bang nucleosynthesis. If we take the tensor-to-scalar ratio on CMB scales to be given by the current observational upper bound, and if we take the ultraviolet cutoff scale in the spectrum of gravitational radiation to be the Planck scale, then the bound is $n_T \lesssim 0.15$, tighter than even Advanced LIGO, the future PPTA, and LISA can hope to achieve. It is not surprising that nucleosynthesis provides the tightest bounds on a blue tilt of the gravitational wave spectrum since nucleosynthesis probes physics on scales much smaller than the other experiments we analyzed, and spectra with blue tilts have more power on the smallest scales. That is, BBN gives us the largest "lever arm" for probing gravitational waves in conjunction with CMB observations, a point also made in [21]. From our results we can clearly see the trend that the bound on the blue tilt of the tensor spectral index tightens as the length scale probed by the given experiment decreases.

Simulations of the angular power spectrum of the temperature anisotropies in the CMB did not offer any tighter constraints on the tensor spectral index, with each of the constraints calculated in this paper producing a temperature power spectrum that was within the cosmic variance error of one calculated for a standard ΛCDM model with tensor modes included.

As mentioned in section 1, equation (2) has been normalized at the scale of cosmic microwave background observations. However, those experiments probe scales that are approximately ten orders of magnitude larger than those probed by the PPTA and approximately nineteen orders of magnitude larger than those probed by LIGO, with LISA probing between the two. Extrapolating between such a large difference in scales is not straightforward and we should note that in [8] the authors conclude from their analysis that even within the framework of the inflationary universe paradigm the formula for the primordial gravitational wave spectrum (2) is too restrictive, and they believe that it is indeed not possible to extrapolate reliably over such a large difference in scales. Whether or not this is the case in the string gas cosmology model should perhaps be examined more carefully in future work.

Continuing with string gas cosmology, we conclude that the current bounds on the tilt of the gravitational wave spectrum are weak. The predicted magnitude of the blue tilt of the gravity wave spectrum is thought to be comparable to the magnitude of the red tilt of the spectrum of scalar metric fluctuations [7]. If the latter is taken to agree with the current bounds, we predict a blue tilt of less than $n_T = 0.1$ which will not be easy to detect. There may, however, be models similar to string gas cosmology in which the scalar and tensor tilts are not related, and for which planned experiments could set valuable constraints on the model parameter space.
