ABSTRACT: Introduction: Limb-girdle muscular dystrophy type 2E (LGMD2E) is caused by mutations in the β-sarcoglycan gene, which is expressed in skeletal, cardiac, and smooth muscles. β-Sarcoglycan-deficient (Sgcβ-null) mice develop severe muscular dystrophy and cardiomyopathy with focal areas of necrosis. Methods: In this study we performed morphological (histological and cellular characterization) and functional (isolation in the murine model of LGMD2E. 

Results: We found that the lack of an immunological system resulted in an increase of calcification in striated muscles without impairing extensor digitorum longus muscle performance. Sgcβ/Rag2-null and Sgcβ/Rag2/c-null muscles showed a significant reduction of alkaline phosphate-positive mesoangioblasts. Discussion: The immunological system counteracts skeletal muscle degeneration in the murine model of LGMD2E.

Muscle Nerve 58: 133–144, 2018

In skeletal and cardiac muscles, dystrophin is associated with sarcolemmal and cytoskeletal proteins forming the dystrophin–glycoprotein complex

Sgcβ/Rag2/c-Null Muscle Analysis
satellite cells, other cell types have been described for muscle regeneration. Mesoangioblasts (MABs) are vessel-associated cells capable of differentiating into several mesodermal lineages, including skeletal muscle and smooth muscle cells.\textsuperscript{12–15} Moreover, MABs constitute an interesting source for stem cell therapies given their renewal abilities and migration properties, and have been characterized also from cardiac tissues.\textsuperscript{13,15,16} Fibroadipogenic progenitors (FAPs) have been found to modulate myogenesis and, eventually, adipogenesis.\textsuperscript{17} Alongside the variety of stem cells that could potentially contribute to the regeneration process, infiltrating inflammatory and immune cells (neutrophils, macrophages, lymphocytes) have a crucial role in the regeneration process. Acute skeletal muscle injury causes an immediate transient wave of neutrophils, followed by a more persistent infiltration of M1 (pro-inflammatory) and M2 (anti-inflammatory/pro-regenerative) macrophages. Injured skeletal muscles are also colonized by different populations of T cells, including T helper lymphocytes (ThL), which have both anti- and pro-fibrotic roles;\textsuperscript{18} T cytotoxic lymphocytes (TcL), responsible for inflammatory response (promoting eosinophilia and fibrosis);\textsuperscript{20,21} and T regulatory lymphocytes (Treg L), which in turn control the inflammatory response by promoting the M1/M2 switch and the activation of satellite cells.\textsuperscript{22}

Previous investigations on animal models of Duchenne muscular dystrophy (DMD) have shown that cellular immune responses by TcL and ThL contribute to muscle pathology, and that removal of specific lymphoid cell populations can reduce muscle pathology. In addition, innate immune responses may also promote muscular dystrophy by infiltration of myeloid cell populations into the dystrophic muscle. Collectively, those earlier studies suggested that the contribution of the immune system to muscular dystrophy may be significant, and that therapeutic approaches based on immune interventions may ameliorate the pathologic progression of dystrophin and sarcoglycan deficiencies.\textsuperscript{20,21}

In Sgcb\textsuperscript{-null} mice, death occurs by heart failure at 16–18 months of age.\textsuperscript{3} Healing of the infarcted heart is associated with intense angiogenesis. The rapid induction of angiogenic growth factors results in formation of a network of hyperpermeable neovessels that may lack a pericyte coat.\textsuperscript{23} As the infarct vascularity matures, some neovessels are coated with pericytes, whereas uncoated vessels regress.\textsuperscript{24} Mature coated vessels protected from regression exhibit decreased inflammatory activity and contribute to scar stabilization.\textsuperscript{25} There are no immunodeficient animal models available for LGMD2E to evaluate the consequences of immune system deficiency in the dystrophic condition. Thus, we have generated a new animal model for this purpose, the Sgcb/Rag2\textsuperscript{-/-} mouse, which lacks functional T, B, and natural killer (NK) cells and is affected by LGMD2E.

The aim of our work was to characterize this new animal model and determine whether immunodeficiency, as just described, affects the dystrophic phenotype.

METHODS

Animal Handling. All protocols were conducted in accordance with the guidelines of the Animal Welfare Committee of KU Leuven Belgian/European legislation and with the ethical approval of KU Leuven (P095/2012). Sgcb/Rag2\textsuperscript{-/-} mice were generated in our laboratory. C57Bl/6J and Rag2\textsuperscript{-/-} mice are used as controls. Four 1-month-old and 4 7-month-old mice were used per strain.

Histological Analyses. Cardiac and skeletal muscles (gastrocnemius and diaphragm) were collected from 1- and 7-month-old C57Bl/6J, Rag2\textsuperscript{-/-}, Sgcb\textsuperscript{-null}, and Sgcb/Rag2\textsuperscript{-/-} mice. Tissues were fixed in 4% paraformaldehyde and embedded in paraffin or cryoconserved in optimum cutting temperature (OCT) compound (Sakura Finetek, Torrance, California) following the manufacturer’s instructions. Hematoxylin-and-eosin (H&E) and Masson trichrome (Sigma-Aldrich, St. Louis, Missouri) staining were performed on 5-μm-thick paraffin slices, and nicotinamide adenine dinucleotide (NADH) transferase staining was performed on 7-μm-thick cryosections, as reported elsewhere.\textsuperscript{26}

Cell Isolation. Cell populations were isolated from hindlimb muscle, including tibialis anterior, gastrocnemius, extensor digitorum longus (EDL), and soleus, and heart biopsies were obtained from 1- and 7-month-old C57Bl/6J, Rag2\textsuperscript{-/-}, Sgcb\textsuperscript{-null}, and Sgcb/Rag2\textsuperscript{-/-} mice. Biopsies were taken and small pieces (approximately 2 × 2 × 2 mm) were cultured on collagen-coated dishes. While spreading cells appeared from fragments, they were carefully removed and cells were detached with TripE (Life Technologies/ Gibco, Grand Island, New York). A large portion of the mixed cell populations obtained from 1- and 7-month-old animals was processed by fluorescence-activated cell sorting (FACS) analysis for sorting alkaline phosphate-positive (AP\textsuperscript{+}) fractions, and a small portion was plated onto collagen-coated Petri dishes and incubated (37°C in a 5% CO\textsubscript{2}, 5% O\textsubscript{2} humidified incubator) for further characterization. AP was used as a specific marker to sort pure MAB populations, as previously described.\textsuperscript{27} MABs, as an AP\textsuperscript{+} cell fraction, were cultured and expanded on collagen-coated plastic in Dulbecco’s modified Eagle medium-20 (DMEM-20) culture medium (DMEM high glucose, 20% fetal calf serum [FCS], 1% penicillin/streptomycin solution [100 units], 2 mmol/L glutamine, 1 mmol/L sodium pyruvate, 1X nonessential amino acid solution, 0.5X β-mercaptoethanol). When cells reached 80%–85% confluence, they were split in a 1:4 ratio. The mixed cell populations were characterized with AP enzymatic staining using 5-bromo-4-chloro-3′-indolylphosphate p-toluidine salt (BCIP) and nitro-blue tetrazolium chloride (NBT) reagent (Sigma-Aldrich). Because we failed to obtain a consistent number of viable cells after cell sorting, mixed cell populations from 7-month-old

\textsuperscript{134} Sgcb/Rag2\textsuperscript{-/-} Mouse Analysis
animals were directly plated and expanded for further characterization.

**Differentiation Assays.** Smooth muscle differentiation was induced in a mixed population and in MABs (AP*) cells) by transforming growth factor-β (TGF-β) treatment (DMEM high glucose, 2% heat-inactivated horse serum [HS], 1% penicillin/streptomycin solution, 2 mmol/L glutamine, 1 mmol/L sodium pyruvate, and 10 ng/ml TGF-β; Peprotech, Oak Park, California). On day 0, 5 × 10⁵ cells/cm², were plated in collagen-coated Petri dishes and incubated at 37°C with DMEM-20 medium. After 24 h, cells were washed with phosphate-buffered saline (PBS), cultured in the smooth muscle differentiation medium, and incubated for 7 days. At the end of differentiation, cultures were fixed with 4% paraformaldehyde (PFA; Sigma Aldrich) in PBS.

**Immunofluorescence Staining.** Immunofluorescence staining was performed following the commonly used steps of Triton-based (Sigma-Aldrich) permeabilization and back-ground blocking with donkey serum (Sigma-Aldrich). Cells or 7-μm-thick crossections were incubated overnight with primary antibodies (reported hereafter) at 4°C and, after washing, 1-h incubation with 1:500 Alexa Fluor-conjugated donkey secondary antibodies (Thermo Fisher Scientific, Waltham, Massachusetts) was performed. Nuclei were counterstained with Hoechst stain.

Primary antibodies and relative dilutions were: smooth muscle actin (α-SMA) Cy3 mouse monoclonal antibody (1:200; Sigma-Aldrich); calponin, rabbit monoclonal antibody (1:200; Abcam, Cambridge, UK); F4/80 (macrophage marker) rat monoclonal antibody (1:200; Abcam); CD206 (mannose receptor) (1:100; Abcam; Sigma-Aldrich); alkaline phosphatase (AP) goat polyclonal antibody (1:500; R&D Systems, Minneapolis, Minnesota); BA-D5 (myosin heavy chain type 1) mouse monoclonal antibody (1:100; Developmental Studies Hybridoma Bank, University of Iowa); and SC-71 (myosin heavy chain type 2a) mouse monoclonal antibody (1:100; Developmental Studies Hybridoma Bank, University of Iowa). Images were acquired microscopically (Eclipse Ti; Nikon, Tokyo, Japan) and morphological analysis was performed with ImageJ software (National Institutes of Health, Bethesda, Maryland).

**Muscle Function by Intact Muscle Test System.** The EDL was immediately excised from each mouse and maintained in a storage solution (Krebs-Ringer bicarbonate buffer, including MgCl₂, KCl, NaCl, Na₂HPO₄, NaH₂PO₄, D-glucose, and NaHCO₃) to which was added potassium phosphate (1.2 mmol/L), magnesium sulfate (0.57 mmol/L), calcium chloride (2.00 mmol/L), and hydroxyethyl piperazine ethane sulfonic acid (10.0 mmol/L), and gassed with a mixture of 95% O₂ and 5% CO₂ at room temperature (pH 7.3 ± 0.3, osmolarity 267 ± 5 mOsm/L). The test was performed in a temperature-controlled (30°C) chamber containing the buffer solution and continuously gassed with a mixture of 95% O₂ and 5% CO₂. One end of the muscle was connected to a fixed clamp while the other end was linked to the lever-arm of a 300B actuator/transducer (Aurora Scientific, Aurora, Ontario, Canada), using a nylon thread. Compliance of the nylon thread and muscle were 0.187 ± 0.004 μm/mN and 2.000 ± 0.082 μm/mN, respectively.

Switching between isometric and isotonic measurements without removing the specimen from the bath was made possible by controlling the force and the position mode of the lever arm.

Two platinum electrodes located about 2 mm from each side of the isolated muscle allowed electrical stimulation with 200-mA controlled-current pulses (pulse voltage approximately 10V). For each experiment, the initial muscle length was adjusted to a length (L₀) that produced the highest twitch force. The muscle cross-sectional area (CSA) was determined by dividing the muscle mass (m) by the product of the optimal fiber length (Lₘ) and the density of mammalian skeletal muscle (1.06 mg/mm³). The Lₘ was determined by multiplying that value of L₀ for the fiber length to the muscle length ratio (0.44 for the EDL) indicated in the literature:

\[ L_m (mm) = L_0 (mm) \times 0.44 \]

\[ CSA (mm^2) = \frac{m (mg)}{L_m (mm) \times 1.06 (mg/mm^3)} \]

The protocol allowed for measurement of isometric and isotonic parameters, inducing the maximum force and fatigue sequence.

The muscle was initially stimulated with a 0.5-ms single pulse to measure the isometric twitch force and contraction time. A second pulse was applied to check the consistency of the values obtained and to balance muscle equilibration before applying tetanic stimulation.

The muscle was then subjected to a first pulse (0.6 s at 120 Hz) to induce unfused tetanus, and then a second pulse (0.6 s at 180 Hz) to evoke the maximal tetanic force.

For measurement of fatigue, muscles were repeatedly stimulated under isotonic conditions with a series pulses (0.4 s at 120 Hz). When the isolated muscle was no longer able to shorten compared with the reference force (one-third of its maximum force), the fatigue test was terminated.

A final isometric stimulus was performed to end the protocol and to determine whether the muscle was damaged after the fatigue sequence. Muscle specimens were weighed after removal of the tendons to calculate CSA values.

**Statistics.** Comparisons between multiple data sets were analyzed by one-way analysis of variance (ANOVA) with Tukey multiple comparison posttests. The Student t-test was used for comparisons between 2 data sets as immunodeficient mice vs. immunocompetent mice. All data were analyzed using GraphPad software (GraphPad Prism version 5.1; GraphPad, Inc., La Jolla, California).

**RESULTS**

Histological Analysis of Skeletal and Cardiac Muscles from Sgcβ/Rag2−/−c-Null Mice. Fibrosis, fiber degeneration, and calcification were present mainly in muscles from immunodeficient (ID)-Sgcβ-null mice. Central nucleated fibers were seen in all dystrophic skeletal muscle sections (Fig. 1A and B). Muscle calcifications were observed directly in intact diaphragms from dystrophic mice compared with wild-type and Rag2−/γ-c-null mice (Fig. 1C). Fibrosis (Fig. 1D) and calcification (Fig. 1E) quantifications were performed using H&E and Masson trichrome staining. In cardiac and diaphragm muscles of ID-Sgcβ-null mice.
FIGURE 1. Histological analysis of gastrocnemius (GCN), diaphragm (DIA), and cardiac muscles from C57Bl/6J, Rag2/c-null mice, IC-Sgcb-null, and ID-Sgcb-null mice. Paraffin sections were obtained from 7-month-old mice and stained with hematoxylin and eosin (H&E) (A) and Masson trichrome (B). Fibrosis, fiber degeneration, and central nucleation of fibers are present only in dystrophic samples (asterisks and arrows, respectively). Similarly, large areas of necrosis and mild fibrosis are seen in dystrophic cardiac muscles. Bar = 50μm. Muscle calcifications (arrows) can be observed directly in intact diaphragms from dystrophic mice (C). Fibrosis quantification (mm²) of gastrocnemius (GCN), diaphragm (DIA), and cardiac muscles is presented as mean ± standard deviation in (D). Calcification in GCN muscles, DIA, and cardiac muscles is reported as mean ± standard deviation in (E). One-way ANOVA test (n = 4): *P < 0.05; **P < 0.01; ***P < 0.001. [Color figure can be viewed at wileyonlinelibrary.com]
FIGURE 2. Inflammatory infiltration in skeletal muscle and cardiac muscles from C57Bl/6J, Rag2/yc null mice, IC-Sgcb null, and ID-Sgcb null mice. Muscle sections were obtained from 7-month-old mice. Distribution of type M1 and M2 macrophages is shown in (A). F4/80Ab was used to identify M1 macrophages (red). CD206-Ab was used to detect M2 macrophages (green). Nuclei were counterstained with Hoechst stain (blue). Bar = 50 μm. M1 macrophage quantification (cells/mm²) in the hindlimb is shown as mean ± standard deviation in (B). M2 macrophage quantification (cells/mm²) in the heart is shown as mean ± standard deviation in (C). Ratio of M2/M1 in hindlimb and heart is shown as mean ± standard deviation in (D). One-way ANOVA test (n = 4): ***P < 0.001. [Color figure can be viewed at wileyonlinelibrary.com]
mice, increased fibrosis was observed when compared with immunocompetent (IC)-Sgcb-null mice, whereas comparable fibrosis was present in the hindlimb muscles of both ID-Sgcb-null and IC-Sgcb-null mice. Calcification areas were absent in control muscles, but were present in ID-Sgcb-null mice compared with IC-Sgcb-null mice, in both skeletal and cardiac muscles.

Findings on infiltration of macrophages M1 and M2, in the hindlimb muscle and heart, are presented in Figure 2A as F4/80-positive and CD206-positive cells, respectively. Cell quantification showed increased amounts of M1 in the hindlimb of ID-Sgcb-null mice compared with controls and IC-Sgcb-null mice (Fig. 2B). In the cardiac muscles, an increase of M2 macrophages in IC-Sgcb-null vs. ID-Sgcb-null mice and controls was observed (Fig. 2C). No differences were observed for M2/M1 ratio in hindlimb and heart (Fig. 2D).

Types of Fibers and Functional Comparisons between Groups. Immunostaining with specific antibodies was performed on cross-sections of gastrocnemius muscles from IC-Sgcb-null, ID-Sgcb-null, and control mice. We were able to distinguish between slow oxidative (Myh1-positive) and fast glycolytic type A (Myh2a-positive; Fig. 3) fibers. Fiber CSA was measured and its percentage distribution, for both fast and slow fibers, is presented in Figure 3. A statistically significant reduction of CSA was found in both dystrophic groups of mice compared with controls for both fiber types, although this was more evident in ID-Sgcb-null mice.

NADH staining on the same samples showed comparable results and further allowed identification of slow oxidative, fast oxidative type A, and fast glycolytic type B fibers (see Fig. S1 in the Supplementary Material online). Quantification of fiber CSA and its percentage distribution again showed a significant reduction for the IC- and ID-Sgcb-null mice compared with
controls (see Fig. S1 online). Mean values of the main morphological parameters of EDL are reported with their standard deviations for both 1- and 7-month assessment in Table S1 (online). However, no significant differences were observed.

We also measured muscle strength of the dystrophic and control mice using electrical stimulation. The mean of maximum forces measured during fused tetanus stimulation at 180 Hz is reported in (A) as maximum force, and normalization by muscle cross-sectional is reported in (B) as specific force. Another specific force, calculated with stimulation at 200 Hz, is reported as a bar chart in (C). The time course of force decline during 40 s of fatiguing stimulation is shown in (D) as fatigue. Data are presented as mean from 1-month-old mice (panels at left) and 7-month-old mice (panels at right) (n = 5). One-way ANOVA test: C57Bl/6J vs. IC-Sgcb-null (‡); Rag2/c null vs. ID-Sgcb null ($) IC-Sgcb null vs. ID-Sgcb null (*) (n = 4); ‡‡,§$ P < 0.01; ‡‡‡,$$$,*** P < 0.001. FIGURE 4. Functional muscle analysis from C57Bl/6J, Rag2/c-null mice, IC-Sgcb-null and ID-Sgcb-null mice. Isometric force measured during a fused tetanus stimulation at 180 Hz is reported in (A) as maximum force, and normalization by muscle cross-sectional is reported in (B) as specific force. Another specific force, calculated with stimulation at 200 Hz, is reported as a bar chart in (C). The time course of force decline during 40 s of fatiguing stimulation is shown in (D) as fatigue. Data are presented as mean from 1-month-old mice (panels at left) and 7-month-old mice (panels at right) (n = 5). One-way ANOVA test: C57Bl/6J vs. IC-Sgcb-null (‡); Rag2/c null vs. ID-Sgcb null ($) IC-Sgcb null vs. ID-Sgcb null (*) (n = 4); ‡‡,§$ P < 0.01; ‡‡‡,$$$,*** P < 0.001. [Color figure can be viewed at wileyonlinelibrary.com]
did not show statistically significant differences between the immunocompetent and immunodeficient dystrophic muscles (Fig. 4C).

The fatigue test, which identifies the force decline only during 40 s of fatiguing stimulation, is reported in Figure 4B. One-month-old EDL muscles from ID-Sgcb-null mice fatigued more rapidly compared with IC-Sgcb-null and wild-type muscles. At 7 months, EDL muscles from both dystrophic mice fatigued at the same rate and more than wild-type muscles. Half-relaxation tension, calculated with maximum and minimum forces, was statistically different between ID-Sgcb-null and the IC-Sgcb-null mouse only at 1 month of age (Table 1).

**Table 1. Functional muscle analysis from C57Bl/6J, Rag2/c-null, IC-Sgcb-null, and ID-Sgcb-null mice**

|                      | C57Bl/6J | Rag2/c-null | IC-Sgcb-null | ID-Sgcb-null |
|----------------------|----------|-------------|--------------|--------------|
| 1 month              |          |             |              |              |
| Fmax (mN)            | 6.16 ± 2.06 | 6.05 ± 0.11 | 6.35 ± 2.65 | 4.43 ± 1.52  |
| Frel (mN)            | 2.05 ± 0.69 | 2.02 ± 0.04 | 2.12 ± 0.88 | 1.48 ± 0.51  |
| Fspect (mN)          | 1.72 ± 0.47 | 2.32 ± 1.03 | 2.79 ± 1.55 | 1.30 ± 0.69  |

Maximum force (Fmax), relative force (Frel), specific force (Fspect), and half-relaxation tension values ± SD are reported for 1-month-old and 7-month-old mice.

One-way ANOVA test: IC-Sgcb null vs ID-Sgcb null (*); C57Bl/6J vs IC-Sgcb null (†). *P < 0.05.
‡‡P < 0.01.

**DISCUSSION**

Previous studies on immunodeficient DMD models showed that loss of T and B cells improved muscle strength and reduced fibrosis in diaphragm and heart. However, clear disadvantages of mdx-based dystrophic animal models include the normal lifespan of these animals and the revertant fibers that affect data interpretation. Indeed, one study showed that Rag2 Il2rb Dmd mice, a non-revertant mutant dystrophin mouse model lacking T, B, and NK cells, had higher creatine kinase levels compared with mdx and wild-type strains. In addition, a severe muscle phenotype was observed in Sgca-null/scid/beige mice, an animal model of LGMD2D in which the scid and beige mutations cause a lack of both T and B lymphocytes and a selective impairment of NK cell functions.

Despite controversy in the literature regarding the impact of the immune system in chronic dystrophic muscle degeneration, there have been no animal models to address this crucial issue in other forms of dystrophy. Thus, in our study, C57Bl/6J mouse models of LGMD2E have been assessed in the presence or absence of a functional immune system. To determine whether the differences found are consequences of the lack of the immune
system and related to dystrophic muscular degeneration, wild-type and immunodeficient mice have been employed for comparison studies. We detected an increase in the pathologic features of dystrophy in ID-Sgcb-null mice compared with IC-Sgcb-null mice. Our results are consistent with other studies that reported an increase in muscle fibrosis in ID dystrophic muscle.\textsuperscript{36,37} In addition, our data show a significant increase in muscle calcification in ID-Sgcb

cardiac and skeletal muscles, especially in the diaphragm, where the areas of calcification were clearly evident in freshly isolated muscles. Ectopic muscle calcification has been described in muscular dystrophy, but we identified a significant increase in muscle calcification in dystrophic mice due to absence of the immune system.

Interestingly, the number of macrophages in the hindlimb muscles tripled in the ID-Sgcb-null
mice compared with the IC-Sgcb-null mice and controls, but there was a sharp decrease in the hearts. Furthermore, M1 and M2 macrophage levels were comparable in the skeletal muscle of IC-Sgcb-null and ID-Sgcb-null animals. These findings are consistent with a previously described accumulation of M1 and M2 macrophages in skeletal muscle after injury, or in a chronic degenerative model of skeletal muscle. Moreover, recent work has shown that M2 macrophages may play a major role in contribution to regeneration of murine infarcted hearts. In this light, a decrease of pro-regenerative macrophages in the heart of ID-Sgcb-null mice may correlate with a worsening of the cardiomyopathy.

FIGURE 6. Smooth muscle differentiation of interstitial cells and pericytes from C57Bl/6J, Rag2/−/−, IC-Sgcb-null, and ID-Sgcb-null mice. Quantification of α-SMA+, calponin+, αSMA/calponin double-positive and double-negative cells from 1-month-old (A) and 7-month-old (B) mice is shown. Immunofluorescence analysis for α-SMA (red) and calponin (green) and quantification of positive cells derived from cardiac and hindlimb pericytes of 1-month-old mice is shown in (C). One-way ANOVA test (n = 5): *P < 0.05; **P < 0.01; ***P < 0.001; Hest: *P < 0.05, **P < 0.01. [Color figure can be viewed at wileyonlinelibrary.com]
In spite of the histologically negative features, functional performance at 7 months of age, when the dystrophic disease has advanced, was not worse in ID-Sgelb-null mice compared with IC-Sgelb-null mice. Functional parameters, including absolute force and fatigue, showed the same loss of force in both dystrophic mouse models compared with controls. However, at 1 month of age, IC-Sgelb-null muscles performed better than ID-Sgelb-null muscles. We hypothesize that the differences observed in functional parameters of 1-month EDL muscles between the ID-Sgelb-null and IC-Sgelb-null animals were probably caused by earlier onset of muscle impairment in the absence of an immune system. It is likely that this discrepancy is lost after several muscle degeneration/regeneration cycles occurring over the course of 6 months.

Different types of resident stem cells have been described as actively participating in tissue regeneration in the skeletal and cardiac muscle interstitia, including MABs.\(^{12,16}\) MABs have been mainly studied for their myogenic capacity. In addition, they have been used for their potential to differentiate very efficiently to smooth muscle cells in vitro for their use as cell substitutes in the heart.\(^{31}\) The authors thank K. P. Campbell (University of Iowa) for providing the Sgelb-null mice.

In response to TGF-\(\beta\), MABs have been shown to differentiate to smooth muscle cells, whereas only 20% did so from wild-type MABs. This strongly suggests that their differentiation potential is altered by the dystrophic environment, which requires more vasculature progenitors for tissue repair. This likely accelerates their differentiation program and in the long run may be responsible for progenitor senescence.\(^{45}\)

In conclusion, we have provided evidence that the immunodeficiency system associated with the dystrophic phenotype results in increased areas of muscle calcification and reduced fiber sizes, without impairing EDL muscle performance. We also observed a decrease in the number of M2 anti-inflammatory macrophages in immunodeficient dystrophic hearts. This may contribute to cardiac degeneration in Sgelb-null mice. Thus, further analysis at a late stage of the disease will be needed to obtain a full understanding of the immune system’s involvement in disease progression.

Ethical Publication Statement: We (the authors) confirm that we have read the Journal’s position on issues involved in ethical publication and affirm that this report is consistent with those guidelines.
