Beyond Data and Model Parallelism for Deep Neural Networks

Zhihao Jia 1  Matei Zaharia 1  Alex Aiken 1

ABSTRACT
Existing deep learning systems commonly parallelize deep neural network (DNN) training using data or model parallelism, but these strategies often result in suboptimal parallelization performance. We introduce SOAP, a more comprehensive search space of parallelization strategies for DNNs that includes strategies to parallelize a DNN in the Sample, Operator, Attribute, and Parameter dimensions. We present FlexFlow, a deep learning engine that uses guided randomized search of the SOAP space to find a fast parallelization strategy for a specific parallel machine. To accelerate this search, FlexFlow introduces a novel execution simulator that can accurately predict a parallelization strategy’s performance and is three orders of magnitude faster than prior approaches that execute each strategy. We evaluate FlexFlow with six real-world DNN benchmarks on two GPU clusters and show that FlexFlow increases training throughput by up to 3.3× over state-of-the-art approaches, even when including its search time, and also improves scalability.

1 Introduction
As deep learning methods have evolved, DNN models have gotten progressively larger and more computationally expensive to train. As a result, it is now standard practice to parallelize DNN training across distributed heterogeneous clusters (Dean et al., 2012; Abadi et al., 2016). Although DNN models and the clusters used to parallelize them are increasingly complex, the strategies used by today’s deep learning frameworks (e.g., TensorFlow, Caffe2, and MXNet) to parallelize training remain simple, and often suboptimal.

The most common parallelization strategy is data parallelism (Krizhevsky et al., 2012), which places a replica of the entire neural network on each device, so that each device processes a subset of the training data, and synchronizes network parameters across replicas at the end of an iteration. Data parallelism is efficient for compute-intensive operators with a few trainable parameters (e.g., convolution) but achieves suboptimal parallelization performance for operators with a large number of parameters (e.g., embedding).

Another common parallelization strategy is model parallelism (Dean et al., 2012), which assigns disjoint subsets of a neural network each to a dedicated device. This approach eliminates parameter synchronization between devices but requires data transfers between operators. ColocRL (Mirhoseini et al., 2017) uses reinforcement learning to learn efficient operator assignments for model parallelism but only explores parallelism in the operator dimension.

We recently proposed OptCNN (Jia et al., 2018), which uses layer-wise parallelism for parallelizing CNNs with linear computation graphs. OptCNN uses dynamic programming to jointly optimize how to parallelize each operator but does not consider parallelism across different operators. Moreover, OptCNN does not apply to many DNNs used for language modeling, machine translation, and recommendations, which tend to be RNNs or other non-linear networks.

In this paper, we introduce a comprehensive SOAP (Sample-Operator-Attribute-Parameter) search space of parallelization strategies for DNNs that generalizes and goes beyond previous approaches. The operator dimension describes how different operators in a DNN are parallelized. For a single operator, the sample and parameter dimensions indicate how training samples and model parameters are distributed across devices. Finally, the attribute dimension defines how different attributes within a sample are partitioned (e.g., the height and width dimensions of an image).

We use SOAP in FlexFlow, a deep learning engine that automatically finds fast parallelization strategies in the SOAP search space for arbitrary DNNs. Existing approaches only consider one or a subset of SOAP dimensions. For example, data parallelism only explores the sample dimension, while OptCNN parallelizes linear CNNs in the sample, attribute and parameter dimensions. FlexFlow considers parallelizing any DNN (linear or non-linear) in all SOAP dimensions and explores a more comprehensive search space that includes existing approaches as special cases. As a result, FlexFlow is able to find parallelization strategies that significantly outperform existing approaches.
The key challenge FlexFlow must address is how to efficiently explore the SOAP search space, which is much larger than those considered in previous systems and includes more sophisticated parallelization strategies. To this end, FlexFlow uses two main components: a fast, incremental execution simulator to evaluate different parallelization strategies, and a Markov Chain Monte Carlo (MCMC) search algorithm that takes advantage of the incremental simulator to rapidly explore the large search space.

FlexFlow’s execution simulator can accurately predict the performance of a parallelization strategy in the SOAP search space for arbitrary DNNs and is three orders of magnitude faster than profiling real executions. We borrow the idea from OptCNN of measuring the performance of an operator once for each configuration and feed these measurements into a task graph that models both the architecture of a DNN model and the network topology of a cluster. The execution simulator estimates the performance of a parallelization strategy by simulating the execution on the task graph. In addition, we introduce a delta simulation algorithm that simulates a new strategy using incremental updates to previous simulations and further improves performance over naive simulations by up to 6.9×.

The execution simulator achieves high accuracy for predicting parallelization performance. We evaluate the simulator with six real-world DNNs on two different GPU clusters and show that, for all the measured executions, the relative difference between the real and simulated execution time is less than 30%. Most importantly for the search, we test different strategies for a given DNN and show that their simulated execution time preserves real execution time ordering.

Using the execution simulator as an oracle, the FlexFlow execution optimizer uses a MCMC search algorithm to explore the SOAP search space and iteratively propose candidate strategies based on the simulated performance of previous candidates. The execution simulator can also work with other search strategies, such as learning-based search algorithms. When the search procedure is finished, the execution optimizer returns the best strategy it has discovered.

We evaluate FlexFlow on a variety of real-world DNNs including AlexNet (Krizhevsky et al., 2012), ResNet-101 (He et al., 2016), Inception-v3 (Szegedy et al., 2016), RNN Text Classification (Kim, 2014), RNN Language Modeling (Zaremba et al., 2014) and Neural Machine Translation (Wu et al., 2016). Compared to data/model parallelism and strategies manually designed by domain experts (Krizhevsky, 2014; Wu et al., 2016), FlexFlow increases training throughput by up to 3.3×, reduces communication costs by up to 5×, and achieves significantly better scaling. In addition, FlexFlow outperforms the strategies found by ColocRL by 3.4-3.8× on the same hardware configuration evaluated in ColocRL. Finally, FlexFlow also outperforms OptCNN, even on linear DNNs, by supporting a larger search space.

### 2 Related Work

**Data and model parallelism** have been widely used by existing deep learning systems to distribute training across devices. Data parallelism (Krizhevsky et al., 2012) is inefficient for operators with a large number of parameters (e.g., densely-connected layers) and becomes a scalability bottleneck in large scale distributed training. Model parallelism (Dean et al., 2012) splits a DNN into disjoint subsets and trains each subset on a dedicated device, which reduces communication costs for synchronizing network parameters but exposes limited parallelism.

**Expert-designed parallelization strategies** manually optimize parallelization for specific DNNs by using experts’ domain knowledge and experience. For example, Krizhevsky (2014) introduces “one weird trick” that uses data parallelism for convolutional and pooling layers and switches to model parallelism for densely-connected layers to accelerate CNNs. To parallelize RNNs, Wu et al. (2016) uses data parallelism that replicates the entire RNN on each node and switches to model parallelism for intra-node parallelization. Although these expert-designed strategies improve performance over data and model parallelism, they are suboptimal. We use these expert-designed strategies as baselines in our experiments and show that FlexFlow can further improve training throughput by up to 2.3×.

**Automated frameworks** have been proposed for finding efficient parallelization strategies in a limited search space. ColocRL (Mirthoseini et al., 2017) uses reinforcement learning to find efficient device placement for model parallelism. OptCNN (Jia et al., 2018) uses dynamic programming to parallelize linear CNNs. OptCNN’s approach does not explore parallelism across operators and is not applicable to DNNs with non-linear computation graphs. Gao et al. (2017; 2019) exploited hybrid parallelization on tiled domain-specific
Table 1 summarizes the parallelism dimensions explored to describe all operators and state in a DNN. Each node operator graph similar to existing deep learning frameworks (e.g., TensorFlow) generalizes Quincy by employing multiple MCMF optimizations for DNNs. To parallelize a DNN operator across devices, we require each device to compute a disjoint subset of the operator’s output tensors. Therefore, we model the parallelization of an operator $o_i$ by defining how the output tensor of $o_i$ is partitioned.

### 3 Overview

Similar to existing deep learning frameworks (e.g., TensorFlow and PyTorch), FlexFlow uses an operator graph $G$ to describe all operators and state in a DNN. Each node $o_i \in G$ is an operator (e.g., matrix multiplication, convolution, etc.), and each edge $(o_i, o_j) \in G$ is a tensor (i.e., a $n$-dimensional array) that is an output of $o_i$ and an input of $o_j$. In addition, FlexFlow also takes a device topology graph $D = (D_N, D_E)$ describing all available hardware devices and their interconnections, as shown in Figure 1. Each node $d_i \in D_N$ represents a device (e.g., a GPU), and each edge $(d_i, d_j) \in D_E$ is a hardware connection (e.g., a NVLink, a PCI-e, or a network link) between device $d_i$ and $d_j$. The edges are labeled with the bandwidth and latency of the connection.

FlexFlow takes an operator graph and a device topology as inputs and automatically finds an efficient strategy in the SOAP search space. All strategies in the search space perform the same computation defined by the DNN and therefore maintains the same model accuracy by design.

The main components of FlexFlow are shown in Figure 1. The execution optimizer uses a MCMC search algorithm to explore the space of possible parallelization strategies and iteratively proposes candidate strategies that are evaluated by an execution simulator. The execution simulator uses a delta simulation algorithm that simulates a new strategy using incremental updates to previous simulations. The simulated execution time guides the search in generating future candidates. When the search time budget is exhausted, the execution optimizer sends the best discovered strategy to a distributed runtime for parallelizing the actual executions.

### 4 The SOAP Search Space

This section introduces the SOAP search space of parallelization strategies for DNNs. To parallelize a DNN operator across devices, we require each device to compute a disjoint subset of the operator’s output tensors. Therefore, we model the parallelization of an operator $o_i$ by defining how the output tensor of $o_i$ is partitioned.
Beyond Data and Model Parallelism for Deep Neural Networks

For each parallelizable dimension in \( \mathcal{P} \), we define its \textit{parallelizable dimensions} \( \mathcal{P}_i \) as the set of all divisible dimensions in its output tensor. \( \mathcal{P}_i \) always includes a \textit{sample} dimension. For all other dimensions in \( \mathcal{P}_i \), we call it a \textit{parameter} dimension if partitioning over that dimension requires splitting the model parameters and call it an \textit{attribute} dimension otherwise.

A \textit{parallelization configuration} \( c_i \) of an operator \( o_i \) defines how the operator is parallelized across multiple devices. Figure 2 shows some example configurations for parallelizing a 1D convolution operator in a single dimension as well as combinations of multiple dimensions.

For each parallelizable dimension in \( \mathcal{P}_i \), \( c_i \) includes a positive integer that is the degree of parallelism in that dimension. \( |c_i| \) is the product of the parallelism degrees for all parallelizable dimensions of \( c_i \). We use equal size partitions in each dimension to guarantee well-balanced workload distributions. A parallelization configuration \( c_i \) partitions the operator \( o_i \) into \( |c_i| \) independent \textit{tasks}, denoted as \( t_{i;1}, \ldots, t_{i|c_i|} \), meanwhile \( c_i \) also includes the device assignment for each task \( t_{i;k} \) (1 \( \leq k \leq |c_i| \)). Given the output tensor of a task and its operator type, we can infer the necessary input tensors to execute each task.

Figure 3 shows an example parallelization configuration for a matrix multiplication operator. The operator is partitioned into four independent tasks assigned to different GPU devices. The input and output tensors of the tasks are shown in the figure.

A \textit{parallelization strategy} \( \mathcal{S} \) describes one possible parallelization of an application. \( \mathcal{S} \) includes a parallelization configuration \( c_i \) for each operator \( o_i \), and each \( o_i \)'s configuration can be chosen independently from among all possible configurations for \( o_i \).

5 Execution Simulator

In this section, we describe the execution simulator, which takes an operator graph \( \mathcal{G} \), a device topology \( \mathcal{D} \), and a parallelization strategy \( \mathcal{S} \) as inputs and predicts the execution time to run \( \mathcal{G} \) on \( \mathcal{D} \) using strategy \( \mathcal{S} \).

The simulator depends on the following assumptions:

A1. The execution time of each task is predictable with low variance and is independent of the contents of input tensors.

A2. For each connection \((d_i, d_j)\) between device \( d_i \) and \( d_j \) with bandwidth \( b \), transferring a tensor of size \( s \) from \( d_i \) to \( d_j \) takes \( s \times b \) time (i.e., the communication bandwidth can be fully utilized).

A3. Each device processes the assigned tasks with a FIFO (first-in-first-out) scheduling policy. This is the policy used by modern devices such as GPUs.

A4. The runtime has negligible overhead. A device begins processing a task as soon as its input tensors are available and the device has finished previous tasks.

To simulate an execution, we borrow the idea from OptCNN (Jia et al., 2018) to measure the execution time of each distinct operator once for each configuration and include these measurements in a \textit{task graph}, which includes all tasks derived from operators and dependencies between tasks. The simulator can generate an execution timeline by running a simulation algorithm on the task graph.

5.1 Task Graph

A \textit{task graph} models dependencies between individual \textit{tasks} derived from operators. To unify the abstraction, we model each hardware connection between devices as a \textit{communication device} that can only perform \textit{communication tasks} (i.e., data transfers). Note that devices and hardware connections are modeled as separate devices, which allows computation (i.e., normal tasks) and communication (i.e., communication tasks) to be overlapped if possible.

Given an operator graph \( \mathcal{G} \), a device topology \( \mathcal{D} \), and a parallelization strategy \( \mathcal{S} \), we use the following steps to construct a task graph \( \mathcal{T} = (\mathcal{T}_N, \mathcal{T}_E) \), where each node \( t \in \mathcal{T}_N \) is a task (i.e., a normal task or a communication task) and each edge \((t_i, t_j) \in \mathcal{T}_E \) is a dependency that task \( t_j \) cannot start until task \( t_i \) is completed. Note that the edges in the task graph are simply ordering constraints—the edges do not indicate data flow, as all data flow is included in the task graph as communication tasks.

1. For each operator \( o_i \in \mathcal{G} \) with parallelization configuration \( c_i \), we add tasks \( t_{i;1}, \ldots, t_{i|c_i|} \) to \( \mathcal{T}_N \).

2. For each tensor \((o_i, o_j) \in \mathcal{G} \), which is an output of operator \( o_i \) and an input of \( o_j \), we compute the output sub-tensors written by tasks \( t_{i;k} \) (1 \( \leq k \leq |c_i| \)) and the
The elapsed time to execute the task.

Figure 4. Simulating an example parallelization strategy. The tasks’ exeTime and device are shown on the top of each column. In Figure 4c and 4d, the word “r” and “s” indicate the readyTime and startTime of each task, respectively, and the dashed edges indicate the nextTask.

Table 3. Properties for each task in the task graph.

| Property | Description |
|----------|-------------|
| exeTime  | The elapsed time to execute the task. |
| device   | The assigned device of the task. |
| sh(t)    | \{t_i[|l_i| t] \in T_k\} |
| o(t)     | \{out[|l_out| t] \in T_k\} |
| readyTime| The time when the task is ready to run. |
| startTime| The time when the task starts to run. |
| endTime  | The time when the task is completed. |
| preTask  | The previous task performed on device. |
| nextTask | The next task performed on device. |
| state    | Current state of the task, which is one of NOTREADY, READY, and COMPLETE. |

For every task pair \(t_i k\) and \(t_j k\) with shared tensors, if the variables are assigned to the same device, we add an edge \((t_i k, t_j k)\) into \(T_E\), indicating a dependency between the two tasks, no communication task is needed. If \(t_i k\) and \(t_j k\) with shared tensors are assigned to different devices, we add a communication task \(t^{c}\) to \(T_N\) and two edges \((t_i k, t^{c})\) and \((t^{c}, t_j k)\) to \(T_E\). The new task \(t^{c}\) is assigned to the communication device between the tasks that perform \(t_i k\) and \(t_j k\), representing a dependency between tasks.

Table 3 lists the properties for each task in the task graph. For a normal task derived from an operator, its exeTime is the time to execute the task on the given device and is estimated by running the task multiple times on the device and measuring the average execution time (assumption A1).

FlexFlow uses a MCMC search algorithm that proposes a new parallelization strategy by changing the parallelization configuration of a single operator in the previous strategy (see Section 6.2). As a result, in the common case, most of the execution timeline does not change from one simulated strategy to the next. Based on this observation, we introduce a delta simulation algorithm that starts from a previous task graph and only re-simulates tasks involved in the portion of the execution timeline that changes, an optimization that dramatically speeds up the simulator, especially for strategies for large distributed machines.
ity queue. Similar to the Bellman-Ford shortest-path algorithm (Cormen et al., 2009), the delta simulation algorithm iteratively dequeues updated tasks and propagates the updates to subsequent tasks.

For the example in Figure 4, consider a new parallelization strategy derived from the original strategy (Figure 4a) by only reducing the parallelism of operator \( o_3 \) to 1 (i.e., \( c_3 = 1 \)). Figure 4d shows the task graph for the new parallelization strategy, which can be generated from the original task graph (in Figure 4c) by updating the simulation properties of tasks in the grey area.

6 Execution Optimizer

The execution optimizer takes an operator graph and a device topology as inputs and automatically finds an efficient parallelization strategy. Using the simulator as an oracle, FlexFlow transforms the parallelization optimization problem into a cost minimization problem, namely minimizing the predicted execution time.

Finding the optimal parallelization strategy is NP-hard, by an easy reduction from minimum makespan (Lam & Sethi, 1977). In addition, the number of possible strategies is exponential in the number of operators of an operator graph (see Section 4), which makes it intractable to exhaustively enumerate the search space. To find a low-cost strategy, FlexFlow uses a cost minimization search to heuristically explore the space and returns the best strategy discovered.

6.1 MCMC Sampling

This section briefly introduces the Metropolis-Hastings algorithm (Hastings, 1970) we use for MCMC sampling in the execution optimizer. The algorithm maintains a current strategy \( S \) and randomly proposes a new strategy \( S^* \), which is accepted and becomes the new current strategy with the following probability:

\[
\alpha(S^*|S) = \min \left( 1, \exp \left( \beta \cdot (\text{cost}(S) - \text{cost}(S^*)) \right) \right)
\]

MCMC tends to behave as a greedy search algorithm, preferring to move towards lower cost whenever that is readily available, but can also escape local minima.

6.2 Search Algorithm

Our method for generating proposals is simple: an operator in the current parallelization strategy is selected at random, and its parallelization configuration is replaced by a random configuration. We use the predicted execution time from the simulator as the cost function in Equation 1 and use existing strategies (e.g., data parallelism, expert-designed strategies) as well as randomly generated strategies as the initial candidates for the search algorithm. For each initial strategy, the search algorithm iteratively proposes new candidates until one of the following two criteria is satisfied: (1) the search time budget for current initial strategy is exhausted; or (2) the search procedure cannot further improve the best discovered strategy for half of the search time.

7 FlexFlow Runtime

We found that existing deep learning systems (e.g., Tensorflow, PyTorch, Caffe2, and MXNet) only support parallelizing an operator in the sample dimension through data parallelism, and it is non-trivial to parallelize an operator in other dimensions or combinations of several SOAP dimensions in these systems.

To support parallelizing DNN models using any strategy in the SOAP search space, we implemented the FlexFlow distributed runtime in Legion (Bauer et al., 2012), a high-performance parallel runtime for distributed heterogeneous architectures, and use cuDNN (Chetlur et al., 2014) and cuBLAS (cuBLAS) as the underlying libraries for processing DNN operators. We use the Legion high-dimensional partitioning interface (Treichler et al., 2016) to support parallelizing an operator in any combination of the parallelizable dimensions.

8 Evaluation

This section evaluates the performance of FlexFlow on six real-world DNN benchmarks and two GPU clusters.

Table 4 summarizes the DNNs used in our experiments. AlexNet, Inception-v3, and ResNet-101 are three CNNs that achieved the best accuracy in the ILSVRC competitions (Russakovsky et al., 2015). For AlexNet, the per-iteration training time is smaller than the time to load training data from disk. We follow the suggestions in TensorFlow Benchmarks * and use synthetic data to benchmark the performance of AlexNet. For all other experiments, the training data is loaded from disk in the training procedure.

RNNTC, RNNLM and NMT are sequence-to-sequence RNN models for text classification, language modeling, and neural machine translation, respectively. RNNTC uses four LSTM layers with a hidden size of 1024. RNNLM uses two LSTM layers with a hidden size of 2048. Both RNN models include a softmax linear after the last LSTM layer. NMT includes an encoder and a decoder, both of which consist of 2 LSTM layers with a hidden size of 1024. To improve model accuracy, we also use an attention layer on top of the last decoder LSTM layer (Bahdanau et al., 2014). Figure 13 illustrates the structure of the NMT model. For all three RNN models, we set the number of unrolling steps for each recurrent layer to 40.

* a top-1 accuracy for single crop on the validation dataset (higher is better).
* b word-level test perplexities on the Penn Treebank dataset (lower is better).
* c BLEU scores (Papineni et al., 2002) on the test dataset (higher is better).

Figure 5. Architectures of the GPU clusters used in the experiments. An arrow line indicates a NVLink connection. A solid line is a PCI-e connection. Dashed lines are Infiniband connections across different nodes.

We follow prior work (Krizhevsky et al., 2012; Szegedy et al., 2016; He et al., 2016; Kim, 2014; Zaremba et al., 2014; Wu et al., 2016) to construct operator graphs and set hyperparameters (e.g., learning rates, weight decays). We use synchronous training and a per-GPU batch size of 64 for all DNN benchmarks, except for AlexNet, which has a much smaller model and uses a per-GPU batch size of 256.

To evaluate the performance of FlexFlow with different device topologies, we performed the experiments on two GPU clusters, as shown in Figure 5. The first cluster contains 4 compute nodes, each of which is equipped with two Intel 10-core E5-2600 CPUs, 256GB main memory, and four NVIDIA Tesla P100 GPUs. GPUs on the same node are connected by NVLink, and nodes are connected over 100GB/s EDR Infiniband. The second cluster consists of 16 nodes, each of which is equipped with two Intel 10-core E5-2680 GPUs, 256GB main memory, and four NVIDIA Tesla K80 GPUs. Adjacent GPUs are connected by a separate PCI-e switch, and all GPUs are connected to CPUs through a shared PCI-e switch. Compute nodes in the cluster are connected over 56 GB/s EDR Infiniband.

Unless otherwise stated, we set 30 minutes as the time budget for the execution optimizer and use data parallelism and a randomly generated strategy as the initial candidates for the search. As shown in Table 5, the search terminates in a few minutes in most cases.

Figure 6. Per-iteration training performance on six DNNs. Numbers in parenthesis are the number of compute nodes used in the experiments. The dash lines show the ideal training throughput.

8.1 Parallelization Performance

8.1.1 Per-iteration Performance

We compare the per-iteration training performance of FlexFlow with the following baselines. Data parallelism is commonly used in existing deep learning systems. To control for implementation differences, we ran data parallelism experiments in TensorFlow r1.7, PyTorch v0.3, and our implementation and compared the performance numbers. Compared to TensorFlow and PyTorch, FlexFlow achieves the same or better performance numbers on all six DNN benchmarks, and therefore we report the data parallelism performance achieved by FlexFlow in the experiments.

Expert-designed strategies optimize parallelization based
on domain experts’ knowledge and experience. For CNNs, (Krizhevsky, 2014) uses data parallelism for parallelizing convolutional and pooling layers and switches to model parallelism for densely-connected layers. For RNNs, (Wu et al., 2016) uses data parallelism that replicates the entire operator graph on each compute node and uses model parallelism that assigns operators with the same depth to the same GPU on each node. These expert-designed strategies are used as a baseline in our experiments. Model parallelism only exposes limited parallelism by itself, and we compare against model parallelism as a part of these expert-designed strategies.

Figure 6 shows the per-iteration training performance on all six DNN benchmarks. For ResNet-101, FlexFlow finds strategies similar to data parallelism (except using model parallelism on a single node for the last fully-connected layer) and therefore achieves similar parallelization performance. For other DNN benchmarks, FlexFlow finds more efficient strategies than the baselines and achieves 1.3-3.3× speedup. Note that FlexFlow performs the same operators as data parallelism and expert-designed strategies, and the performance improvement is achieved by using faster parallelization strategies. We found that the parallelization strategies discovered by FlexFlow have two advantages over data parallelism and expert-designed strategies.

Reducing overall communication costs. Similar to existing deep learning systems, the FlexFlow distributed runtime supports overlapping data transfers with computation to hide communication overheads. However, as we scale the number of devices, the communication overheads increase, but the computation time used to hide communication remains constant. Therefore, reducing overall communication costs is beneficial for large-scale distributed training. Figure 7a shows that, to parallelize the NMT model on 64 K80 GPUs (16 nodes), FlexFlow reduces the per-iteration data transfers by 2-5.5× compared to other parallelization approaches.

Reducing overall task computation time. Data parallelism always parallelizes an operator in the batch dimension. However, as reported in (Jia et al., 2018), parallelizing an operator through different dimensions can result in different task computation time. For the matrix multiplication operator in the NMT model, parallelizing it in the channel dimension reduces the operator’s overall computation time by 38% compared to parallelizing the operator in the batch dimension. Figure 7b shows that FlexFlow reduces the overall task computation time by 20% compared to data parallelism for the NMT model. The expert-designed strategy achieves slightly better total task computation time than FlexFlow. However, this is achieved by using model parallelism on each node, which disables any parallelism within each operator and results in imbalanced workloads. As a result, the expert-designed strategy achieves even worse execution performance than data parallelism (see Figure 7a). FlexFlow reduces the task computation time while enabling parallelism within an operator and maintaining load balance.

8.1.2 End-to-end Performance

FlexFlow performs the same computation as other deep learning systems for a DNN model and therefore achieves the same model accuracy. Table 4 verifies that FlexFlow achieves the state-of-the-art accuracies on the DNN benchmarks used in the experiments.

In this experiment, we compare the end-to-end training performance between FlexFlow and TensorFlow on Inception-v3. We train Inception-v3 on the ImageNet dataset until the model reaches the single-crop top-1 accuracy of 72% on the validation set. The training processes in both frameworks use stochastic gradient descent (SGD) with a learning rate of 0.045 and a weight decay of 0.0001. Figure 8 illustrates the training curves of the two systems and show that FlexFlow reduces the training time by 38% compared to TensorFlow.
8.1.3 Automated Frameworks

We compare against two automated frameworks that find parallelization strategies in a limited search space.

**ColocRL** uses reinforcement learning to learn device placement for model parallelism. We are not aware of any publicly available implementation of ColocRL, so we compare against the learned device placement for Inception-v3 and NMT, as reported in the paper, and performed the experiments on the same machine.

Figure 9a compares the training throughput of the strategies found by FlexFlow and ColocRL for four K80 GPUs on a single node. The parallelization strategies found by FlexFlow achieve 3.4 – 3.8× speedup compared to ColocRL. We attribute the performance improvement to the larger search space explored by FlexFlow.

Besides improving training performance, FlexFlow has two additional advantages over ColocRL. First, ColocRL requires executing each strategy in the hardware environment to get reward signals and takes 12-27 hours to find the best placement, while FlexFlow finds efficient parallelization strategies for these executions in 14-40 seconds. Second, ColocRL uses up to 160 compute nodes (with 4 GPUs on each node) to find the placement in time, while FlexFlow uses a single compute node to run the execution optimizer.

**OptCNN** (Jia et al., 2018) uses dynamic programming to parallelize linear DNNs. To evaluate OptCNN’s performance on non-linear RNNs, we explicitly fuse all recurrent nodes sharing the same parameters to a single operator.

We compare the performance of FlexFlow and OptCNN for different DNNs on 16 P100 GPUs. FlexFlow and OptCNN found the same parallelization strategies for AlexNet and ResNet with linear operator graphs and found different strategies for the other DNNs as shown in Figure 9b. For these DNNs with non-linear operator graphs, FlexFlow achieves 1.2-1.6× speedup compared to OptCNN by using parallelization strategies that exploit parallelism across different operators. We show two examples in Section 8.4.

8.2 Execution Simulator

We evaluate the performance of the simulator using two metrics: simulator accuracy and simulator execution time.

**Simulator accuracy.** We first compare the estimated execution time predicted by the execution simulator with the real execution time measured by actual executions. Figure 10 shows the results for different DNNs and different available devices. The dashed lines indicate a relative difference of 0% and 30%, respectively, which encompasses the variance between actual and predicted execution time. In addition, for different parallelization strategies with the same operator graph and device topology (i.e., points of the same shape in the figure), their simulated execution time preserves actual execution time ordering, which shows that simulated execution time is an appropriate metric to evaluate the performance of different strategies.

**Simulator execution time.** Figure 11 shows the search performance with different simulation algorithms for the NMT model on 16 P100 GPUs (4 nodes).
Beyond Data and Model Parallelism for Deep Neural Networks

Figure 12. The best discovered strategy for parallelizing Inception-v3 on 4 P100 GPUs. For each operator, the vertical and horizontal dimensions indicate parallelism in the sample and parameter dimension, respectively. Each GPU is denoted by a color.

Figure 13. The best discovered strategy for parallelizing NMT on 4 P100 GPUs. For each operator, the vertical and horizontal dimensions indicate parallelism in the sample and parameter dimension, respectively. Each grey box denotes a layer, whose operators share the same network parameters. Each GPU is denoted by a color.

8.3 Search Algorithm

We compare the best discovered strategies with the global optimal strategies for small executions. To obtain a search space of reasonable size, we limit the number of devices to 4 and consider the following two DNNs. LeNet (LeCun, 2015) is a 6-layer CNN. The second DNN is a variant of RNNLM where the number of unrolling steps for each recurrent layer is restricted to 2. We use depth-first search to explore the space and use A* (Cormen et al., 2009) to prune the search. Finding the optimal strategies for LeNet and RNNLM took 0.8 and 18 hours, respectively. For both DNNs, FlexFlow finds the same global optimal strategy in less than 1 second.

8.4 Case Studies

Inception-v3. Figure 12 shows the best discovered strategy for parallelizing Inception-v3 on four P100 GPUs, which exploits intra-operator parallelism for operators on the critical path and uses a combination of intra- and inter-operator parallelism for operators on different branches. This results in a well-balanced workload and reduces data transfers for parameter synchronization. Compared to data parallelism, this strategy reduces the parameter synchronization costs by 75% and the per-iteration execution time by 12%.

For parallelizing the same Inception-v3 model on four K80 GPUs with asymmetric connections between GPUs (see Figure 5b), we observe that the best discovered strategy tends to parallelize operators on adjacent GPUs with a direct connection to reduce the communication costs.

NMT. Figure 13 shows the best discovered strategy for parallelizing NMT on four P100 GPUs. First, for a layer with a large number of network parameters and little computation (e.g., embed layers), it performs the computation on a single GPU to eliminate parameter synchronization. Second, for a layer with a large number of parameters and heavy computation (e.g., softmax layers), FlexFlow uses parallelism in the parameter dimension and assigns the computation for a subset of parameters to each task. This reduces parameter synchronization costs while maintaining load balance. Third, for multiple recurrent layers (e.g., LSTM and attention layers), FlexFlow uses concurrency among different layers as well as parallelism within each operator to reduce parameter synchronization costs while balancing load.

9 Conclusion

This paper presents FlexFlow, a deep learning system that automatically finds efficient parallelization strategies in the SOAP search space for DNN training. FlexFlow uses a guided randomized search procedure to explore the space and includes an execution simulator that is an efficient and accurate predictor of DNN performance. We evaluate FlexFlow with six real-world DNN benchmarks on two GPU clusters and show FlexFlow significantly outperforms state-of-the-art parallelization approaches.

Algorithm 1 shows the pseudocode of the full simulation algorithm. It first builds a task graph using the method described in Section 5.1 and then sets the properties for each task using a variant of Dijkstra’s shortest-path algorithm (Section 24.1 of Cormen et al. (2009)). Tasks are enqueued into a global priority queue when ready (i.e., all predecessor tasks are completed) and are dequeued in increasing order by their readyTime. Therefore, when a task is dequeued, all tasks with an earlier readyTime have been scheduled, and we can set the properties for task while maintaining the FIFO scheduling order (assumption A3).

B Delta Simulation Algorithm

Algorithm 2 shows the pseudocode of the full simulation algorithm. It first updates tasks and dependencies from an existing task graph and enqueues all modified tasks into a global priority queue (line 4-5). Similar to the Bellman-Ford shortest-path algorithm (Section 24.1 of Cormen et al. (2009)), the delta simulation algorithm iteratively dequeues updated tasks and propagates the updates to subsequent tasks (line 6-14). The full and delta simulation algorithms always produce the same timeline for a given task graph.

C Artifact Appendix

C.1 Abstract

This artifact appendix helps readers to reproduce the main experimental results in this paper. In the artifact evaluation, we compare the average training throughput of different parallelization strategies in FlexFlow.

C.2 Artifact check-list (meta-information)

- **Compilation:** GCC 4.8 or above, CUDA 8.0 or above, cuDNN 6.0 or above
- **Run-time environment:** Linux Ubuntu 16.04 or above
- **Hardware:** A compute node with multiple GPUs, such as Amazon EC2 p2.xlarge or p3.xlarge instances. Note that a single GPU is able to verify the functionality of FlexFlow but cannot show FlexFlow’s performance improvement over the baselines (e.g., data parallelism).
- **Metrics:** The primary metric of comparison is the average training throughput.
Algorithm 2 Delta Simulation Algorithm.

1: **Input:** An operator graph $G$, a device topology $D$, an original task graph $T$, and a new configuration $c'_i$ for operator $o_i$.
2: updateQueue = {} // a priority queue sorted by readyTime
3: /*UPDATE TASKGRAPH returns the updated task graph and a list of tasks with new readyTime*/
4: $T, L = UPDATE TASKGRAPH(T, G, D, c_i, c'_i)$
5: updateQueue.enqueue($L$)
6: while updateQueue $\neq \{}$ do
7: Task $t = updateQueue.dequeue()$
8: $t.startTime = \max\{t.readyTime, t.preTask.endTime\}$
9: $t.endTime = t.startTime + t.exeTime$
10: for $n \in O(t)$ do
11: if UPDATE TASK($n$) then
12: updateQueue.push($n$)
13: if UPDATE TASK($t.nextTask$) then
14: updateQueue.push($t.nextTask$)
15: return $\max\{t.endTime | t \in T_N\}$
16:
17: function UPDATE TASK($t$)
18: $t.readyTime = \max\{p.endTime | p \in I(t)\}$
19: /*Swap t with other tasks on the device to maintain FIFO.*/
20: $t.startTime = \max\{t.readyTime, t.preTask.endTime\}$
21: if t’s readyTime or startTime is changed then
22: return True
23: else
24: return False

- How much disk space required (approximately)?: About 2 GB of disk storage should be sufficient for all experiments.
- How much time is needed to prepare workflow (approximately)?: About one hour to install all dependencies and compile the FlexFlow runtime.
- How much time is needed to complete experiments (approximately)?: About 20 minutes for all experiments.
- Publicly available?: Yes
- Code licenses (if publicly available?): Apache License, Version 2.0.
- Archived (provide DOI)?: https://doi.org/10.5281/zenodo.2564262

C.3 Description

C.3.1 Hardware dependencies

The experiments in the paper were performed on two GPU clusters, as described in Figure 5. To reproduce the experiments, we suggest to run this artifact evaluation on a compute node with multiple GPUs, such as Amazon EC2 p2.xlarge or p3.xlarge instances. This will be sufficient to demonstrate FlexFlow’s performance improvement over the widely used data parallelism baseline.

C.3.2 Software dependencies

FlexFlow depends on the following software libraries:

- NVIDIA cuDNN and cuBLAS libraries are used to perform DNN operations.
- Legion (Bauer et al., 2012) is the underlying runtime FlexFlow built on.
- (Optional) GASNet ¹ is used for distributed executions.

The following software versions were used in our experiments:

cuDNN 7.3, CUDA 9.0, Legion 18.02.0, and GASNet 1.28.0.

C.4 Installation

The README.md file includes detailed instructions on how to install the FlexFlow runtime. The Legion and GASNet submodules can be initialized by the following command lines:

git submodule init
git submodule update

The ffcompile.sh script compiles a DNN model in FlexFlow:

```
./ffcompile.sh dnn.cc
```

where dnn.cc defines the operators in the DNN model.

C.5 Experiment workflow

The run_experiments.sh script automatically builds and evaluates two example DNN models (i.e., AlexNet (Krizhevsky et al., 2012) and ResNet (He et al., 2016)) in FlexFlow. All experiments were run with synthetic data in GPU memory to remove the side effects of data transfers between CPU and GPU.

For each DNN model, we compare the training throughputs of data parallelism and FlexFlow’s optimized parallelization strategies on 1, 2, and 4 GPUs on a compute node.

C.6 Evaluation and expected result

The run_experiments.sh script prints the training throughputs of different parallelization strategies. By running the script on a multi-GPU node, you should observe that FlexFlow’s optimized strategies consistently outperform the data parallelism baseline.

C.7 Experiment customization

FlexFlow can be used to optimize parallelization for arbitrary DNN models. We refer users to the README.md file in this artifact evaluation for detailed instructions on how to use FlexFlow for other DNN models.
