**ABSTRACT:** Amylases are key enzymes in the processing of starch in many kingdoms of life. They are important catalysts in industrial biotechnology where they are applied in, among others, food processing and the production of detergents. In man amyloses are the first enzymes in the digestion of starch to glucose and arguably also the preferred target in therapeutic strategies aimed at the treatment of type 2 diabetes patients through down-tuning glucose assimilation. Efficient and sensitive assays that report selectively on retaining amylase activities irrespective of the nature and complexity of the biomaterial studied are of great value both in finding new and effective human amylase inhibitors and in the discovery of new microbial amylases with potentially advantageous features for biotechnological application. Activity-based protein profiling (ABPP) of retaining glycosidases is inherently suited for the development of such an assay format. We here report on the design and synthesis of 1,6-epi-cyclophellitol-based pseudodisaccharides equipped with a suite of reporter entities and their use in ABPP of retaining amylases from human saliva, murine tissue as well as secretomes from fungi grown on starch. The activity and efficiency of the inhibitors and probes are substantiated by extensive biochemical analysis, and the selectivity for amylases over related retaining endoglycosidases is validated by structural studies.

**INTRODUCTION**

Retaining α-amylases, belonging to the glycose hidrolase (GH) 13 family (www.cazy.org),1 are starch-processing enzymes present in plants, animals, and microorganisms.2–4 They catalyze the hydrolysis of internal α-1,4-glycosidic linkages in starch and related polysaccharides through a two-step Koshland double displacement mechanism (Figure S2A). In this mechanism, the aglycon is protonated by the general acid/base residue, followed by $S_\text{N}2$ nuclease attack by the catalytic nucleophile at the anomeric center to form a covalent enzyme–substrate intermediate with inversion of anomeric configuration. The covalent enzyme–substrate adduct is subsequently hydrolyzed to yield oligosaccharide products (for instance linear and α-1,6-branched malto-oligosaccharides) with net retention of α-anomeric configuration.5

Starch is the main product of major human and animal feedstock crops including wheat, rice, maize, tapioca, and potato. Traditionally, large-scale starch processing, an industry established over 100 years ago, relied on the degradation of starch by acid hydrolysis.6,7 Amylases have gained considerable traction as alternatives to conventional chemical starch hydrolysis, as they are more environmentally benign, are less energy intensive, and moreover may produce more defined oligosaccharide products from starch polymers.8,9 Today, a large number of α-amylases from microbial sources are commercially available and are widely used for the production of high glucose and fructose syrups.10,11 Another major application of α-amylases is found in the detergent industry, where they act at low temperatures and alkaline pH to remove tough starch stains from clothes and porcelains under mild conditions.12 α-Amylases are furthermore extensively employed in textile, food, paper, and biofuel industries. The α-amylases currently applied in industrial biotechnology originate from a limited number of fungal and bacterial strains, including *Aspergillus oryzae* and *Bacillus licheniformis*.1,12 The microbial world however may harbor many additional α-amylases including ones that differ functionally in terms of activity, substrate specificity, and resistance to (harsh) biotechnological conditions.

In addition to their potential in biotechnological applications, α-amylases have received increased interest in the past decades in the context of human health. In mammals, digestion of starch by salivary and pancreatic α-amylases leads to linear and branched malto-oligosaccharides. These are largely hydrolyzed to glucose by α-glucosidases located in the intestinal brush border membrane of the small intestine. These α-glucosidases are also targets for therapeutics in the treatment of type 2 diabetes patients through down-tuning glucose assimilation.7,13

mucosa, which then enters the bloodstream by means of facilitated diffusion. Control of postprandial glucose levels, which has proven to be a key factor for the treatment of diabetes and obesity,14 might be achieved by activity modulation of starch-processing enzymes. Anti-diabetic drugs currently used in the clinic include the \( \alpha \)-glucosidase inhibitors,15,16 miglitol, voglibose, and acarbose, the last of which also inhibits human pancreatic \( \alpha \)-amylase (HPA).17,18 However, their effectiveness is offset by undesirable side effects, including diarrhea, flatulence, and abdominal pain, secondary effects that arise predominantly from inhibition of intestinal \( \alpha \)-glucosidases. Hence, selective inhibitors targeting exclusively HPA, the first enzyme in the digestion sequence, would be of great interest.19–24

Activity-based protein profiling (ABPP) has emerged as a powerful strategy to obtain qualitative and quantitative activity information on enzymes of interest in complex mixtures.25,26 ABPP is especially useful for retaining glycosidases that form a covalent enzyme–substrate intermediate during hydrolysis. It relies on the availability of suitable activity-based probes (ABPs) that are generally generated from covalent and irreversible inhibitors by equipping these with a reporter entity (a fluorophore or biotin) or a bio-orthogonal tag. By means of ABPP, enzyme activities can be rapidly identified and quantified (comparative ABPP) and the effect of inhibitors on target enzymes studied in cell extracts and living cells (competitive ABPP). Our work on retaining glycosidase ABPP is rooted in the known mechanism-based \( \beta \)-glucosidase inhibitor cyclophellitol, isolated from Phellinus sp.27 In the first instance we applied cyclophellitol-derived ABPs to the study of retaining \( \alpha \)–acting \( \alpha \)- and \( \beta \)-glycosidases.28–32 More recently, we expanded the methodology toward retaining endoglycosidases in our work on xylobiose-configured ABPs to investigate \( \alpha \)–acting xylanases.33,34 Here, we reveal the efficacy of retaining glycosidase ABPP by the design and chemical synthesis of a panel of maltobiose \( \alpha \)-cyclophellitol derived retaining \( \alpha \)-amylase inhibitors and ABPs, the kinetic and structural analysis of their interactions with microbial \( \alpha \)-amylases, and the application of these probes for rapid detection and identification of \( \alpha \)-amylases in fungal secretomes, mouse tissue, and human saliva. Our work complements a recent35 study by Withers and colleagues, who reported a chemoenzymatic synthesis of maltobiose \( \alpha \)-cyclophellitol, to which we could match our chemically derived material and as well our structural work on \( \alpha \)-amylase-inhibitor complexes. Our results moreover illustrate the potential of retaining \( \alpha \)-amylase ABPP in the annotation of \( \alpha \)-amylases in complex biological samples.

## RESULTS AND DISCUSSION

### Design and Synthesis of \( \alpha \)-Amylase Inhibitors and Activity-Based Probes

We have previously revealed that 1,6-\( \alpha \)-cyclophellitol and its aziridine and cyclic sulfate analogues (Figure 1A) are potent mechanism-based \( \alpha \)-glucosidase inhibitors and that their tagged versions are effective activity-based retaining \( \alpha \)-exoglucosidase probes.36–38 These monosaccharidic cycloittol however do not inhibit \( \alpha \)–acting \( \alpha \)-amylases, which we argued is because of the absence of productive binding with the larger \( \alpha \)-glycosidase active sites (Figure S2C). In line with this consideration, Withers and co-workers subsequently reported that the maltose disaccharide mimetic \( \alpha \)-1,4-glycopyranosyl \( \alpha \)-cyclophellitol (compound 1a, Figure 1B), which they prepared by enzymatic \( \alpha \)-glycosylation of 1,6-\( \alpha \)-cyclophellitol, is an effective mechanism-based, covalent, and irreversible HPA inhibitor.34

Crystallographic analysis of an HPA–inhibitor complex points to the O4’ of the nonreducing end sugar, which may simply be alkylated to block potential exoglycosidase action as a promising site for orthogonal functionalization (as in 1b) to allow introduction of a reporter entity (a fluorophore or biotin, as in 1c and 1d). Alternatively and in line with our previous work on xylanase ABPs, we envisaged the design of maltose-configured cyclophellitol aziridines bearing the reporter tag on the aziridine nitrogen, either with or without an O4’ cap (compounds 2a–2c, Figure 1B). Finally and in line with our previous results on 1,6-\( \alpha \)-cyclophellitol cyclosulfate being a potent and selective retaining \( \alpha \)-exoglucosidase inhibitor,36,37 we decided to produce the corresponding maltose cyclosulfate (compound 3a, Figure 1B) as well with the aim to investigate whether this Michaelis complex emulating inhibitor would also act on amylases.

We have recently reported the synthesis of xylo-cyclophellitols via the direct glycosylation of xylo-cyclophellitol (aziridine) acceptors.33 This route however appeared not feasible for the construction of compounds 1a–d since the epoxide functionality in partially protected 1,6-\( \alpha \)-cyclophellitols proved unstable toward stoichiometric amounts of Lewis acid under the conditions required to effect formation of \( \alpha \)-1,4-glycosidic bonds using contemporary glycosylation conditions. Alternatively, cyclohexene 5 was found to readily undergo glycosylation with imidate donor 4a under \( N,N \)-dimethyleformamide (DMF) and trifluoromethanesulfonic acid (TIOH) activating conditions, affording pseudodisaccharide 6a in good yield.30 Selective deprotection of the 4-methoxymethyl group in 6a followed by epoxidation afforded an inseparable mixture of \( \alpha \)/\( \beta \)-epoxides in a 1:3 ratio, which were silylated and separated by silica gel column chromatography to yield pure 8a and 9a. Desilylation and global debenzylization of 8a by Pearlman’s catalyst hydrogenation gave maltobiose cyclophellitol 1a, of which all analytical and spectroscopical data proved to match those of the chemoenzymatically produced compound.24 The epoxide in 9a was converted to aziridine 14a by treatment with sodium azide followed by a Staudinger-type

---

**Figure 1.** Design of mechanism-based retaining \( \alpha \)-glucosidase inhibitors and ABPs: (A) structures of retaining \( \alpha \)-exoglucosidase inhibitors; (B) structures of retaining \( \alpha \)-amylase inhibitors and ABPs, which are subject of the here-described studies.
Thus, we hypothesized that hydrolysis by exo-xylobiose-cyclophellitol aziridine probe was susceptible to epimerization during the catalysis, giving 4a. The same strategy was also applied to construct maltobiose cyclopentafulvalenes with an ethyl cap as a fluorophore or biotin moiety, ABPs 1d and 1e were obtained, respectively.

The same strategy was also applied to construct maltobiose epicyclophellitol cyclosulfate 3a. Intramolecular glycosylation with acceptor 5 under N-iodosuccinimide (NIS)/DMF/TIOH conditions, giving 4-ethyl pseudodisaccharide 6b in good yield. Following the same route as for 2a, 4'-ethyl capped maltobiose epicyclophellitol aziridine 16 could be readily obtained from intermediate 9b, which was equipped with a Cy5 fluorophore to produce ABP 2b (Scheme 1).

Our previous studies on endo-xylanases revealed that the xylobiose-cyclophellitol aziridine probe was susceptible to hydrolysis by exo-xylosidases present in Aspergillus secretomes. Thus, we hypothesized that “capping” the O4' position of maltobiose epicyclophellitol azirines with an ethyl group would prevent cleavage by exo-acting α-glucosidases in complex biological samples. This was achieved by using O4' ethyl capped thiophenyl donor 4b for glycosylation with acceptor 5 under N-iodosuccinimide (NIS)/DMF/TIOH catalysis, giving 4'-ethyl pseudodisaccharide 6b in good yield. Following the same route as for 2a, 4'-ethyl capped maltobiose epicyclophellitol aziridine 16 could be readily obtained from intermediate 9b, which was equipped with a Cy5 fluorophore to produce ABP 2b. We constructed epoxide-based ABPs by using thiophenyl donor 4c, where the azidooctyl group was introduced in an early stage for later installation of reporter entities and also to prevent exo-glycosidase processing.
a pair of catalytic active site residues (Asp206 as a nucleophile and Glu230 as the acid/base) to cleave amylose chains and requires several subsites to be occupied to catalyze hydrolysis at meaningful rates.\textsuperscript{39}

To assess time-dependent inhibition, the hydrolysis of 2-chloro-4-nitrophenyl maltotrioside (CNP-M3) by Taka-amylase was measured after preincubation with 2 mM of inhibitors 1\textsubscript{a}, 1\textsubscript{b}, 2\textsubscript{a}, and 3\textsubscript{a}. All four inhibitors displayed a time-dependent inhibition of Taka-amylase; however the rates of inhibition varied greatly (Figure 2). Both the epi-cyclophellitol epoxide 1\textsubscript{a} and aziridine 2\textsubscript{a} had slow rates of inactivation, with rate constants of 0.0061 $\pm$ 0.0002 min$^{-1}$ and 0.005 $\pm$ 0.002 min$^{-1}$, respectively. The rate constant for the inactivation by 1\textsubscript{a} is somewhat higher than was previously observed for its inhibition of HPA, determined to be 0.001 min$^{-1}$ at a higher concentration of inhibitor (3.6 mM).\textsuperscript{24} It is somewhat surprising that the aziridine had a rate of inhibition slightly worse than that of the epoxide, as our previous work somewhat surprising that the aziridine had a rate of inhibition somewhat higher than was previously observed for acarbose.\textsuperscript{41}

The crystal structure of 1\textsubscript{a} bound to the active site nucleophile (Asp206) showed the cyclitol moiety to adopt a $^4C_1\text{ff}$ chair conformation, which is also observed for 1\textsubscript{b} and 3\textsubscript{a}. This conformation matches that observed for the $^{-1}$ sugar by Caner et al.\textsuperscript{24} for the binding of enzymatically synthesized 1\textsubscript{a} to HPA and the conformation of an in situ generated 5-fluoro-idose trisaccharide, also to HPA.\textsuperscript{73} Although a detailed computational analysis of the conformational itineraries for a GH13 $\alpha$-amylase has yet to be done, a detailed analysis of a homologous GH13 amylucrase from \textit{Neisseria polysaccharea} has been published.\textsuperscript{40} This analysis proposes a $^4C_1\text{ff}$ trajectory for the glycosylation step, consistent with the observed conformation of the inhibitor bound in the $^{-1}$ position. The nucleophile, Asp206, in the 1\textsubscript{a} complex structure is present in two conformations, one minor unbound conformation which aligns with the uncomplexed form (PDB code 6YQ7) and the other rotated approximately 120$^\circ$ from the uncomplexed orientation that we ascribe to the conformation present in the covalently inhibited enzyme (Figure 3, panel A, PDB code 6YQ9). This second conformation is also seen for the 1\textsubscript{b} complex which is at full occupancy. Bound 1\textsubscript{a} also forms nine direct hydrogen bonds with Taka-amylase (with His122, Arg204, Thr207, His296, and Asp297 in the $^{-1}$ subsite and Thr83, Asp340, and Arg344 in the $^{-2}$ subsite), replicating those seen in the structure of a complex between Taka-amylase and acarbose (PDB code 7TAA), with the exception of the hydrogen bond between the 6-OH of 1\textsubscript{a} and Thr207, and the lack of an H-bond with the catalytic nucleophile that is observed for acarbose.\textsuperscript{41}

The structure of 4$'$-alkylamine epi-cyclophellitol 1\textsubscript{b} bound in the active site (Figure 3, panel B, PDB code 6YQC) maintains an identical hydrogen bonding network to that seen in the complex with 1\textsubscript{a}, the only difference being the complete occupancy of the inhibitor, resulting in the absence of an unbound Asp206 conformer and the presence of an alkyl tail. The 4$'$ tail of 1\textsubscript{b} can only be modeled to the sixth carbon (away from the maltose core) indicating that the terminal amine may form multiple interactions in the $^{-3}$ subsite. This portion of the alkyl tail that could be modeled with confidence is appropriately positioned to form a C=H/$\pi$ hydrogen bond through the second carbon which is 3.9 Å away from Tyr75. This interaction may in part be responsible for better binding of 1\textsubscript{b} to Taka-amylase and the resulting increased rate of inhibition.

The structure of the epi-cyclophellitol cyclosulfate 3\textsubscript{a} complex has many similarities with complexes of the epoxide inhibitors 1\textsubscript{a} and 1\textsubscript{b} (Figure 3, panel C, PDB code 6YQB).
The cyclitol is covalently attached to Asp206, again rotated approximately 120° from the unreacted enzyme, and is in a $^4\text{C}_1$ conformation. The $-2$ sugar is positioned exactly as for 1a, however the presence of an exocyclic sulfur at the 6 position has resulted in Thr207 being positioned within hydrogen bonding distance to the O6 that forms the sulfate ester. The sulfate group is also positioned within hydrogen bonding distance to the acid/base residue, Glu230; however this residue appears in two different conformations in the structure.

Binding of 2a to Taka-amylase is strikingly dissimilar to the other three inhibitor complexes (Figure 3, panel D, PDB code 6YQA). The inhibitor is again covalently bound to Asp206; however the nucleophile is rotated nearly 180° when compared to the other three complexes such that the nonbonded O6 is positioned above the $\beta$ face of the bound cyclitol ring rather than below it. The hydrogen bonds between the inhibitor and the enzyme $-1$ subsite are also altered, with the cyclitol methoxy alcohol rotated to form a hydrogen bond with Thr207 (instead of His122), and the C6 nitrogen forms a hydrogen bond with the acid/base residue (Glu230). Furthermore, the reacted cyclitol, rather than $^4\text{C}_1$, is in an unprecedented $E_3$ conformation, the emergence of which we attribute to the presence of the alkyl-chain. We have observed that cyclophellitol aziridines with N-alkylation are generally well accepted in both $exo$-acting enzymes as these often have open + subsites $^{28-32}$ and $endo$-acting enzymes that target $\beta$-linkages, $^{33}$ which typically contain long, tunnel, or groove-like active sites. The active site of Taka-amylase, conversely, is a V-shaped surface depression with a severe angle between the $-1$ and +1 sugar binding sites; this in turn constrains the conformation of the aziridine alkylation and the conformation of the cyclitol ring.

**In Vitro Labeling of Recombinant Human Saliva $\alpha$-Amylase with ABPs 1c, 2b, and 2c.** With the fluorescent
ABPs 1c, 2b, and 2c in hand, we first investigated their labeling efficiency and specificity toward recombinant human saliva α-amylase (type XIII-A, HSA). Kinetic analysis for inactivation of Taka-amylase revealed the parent inhibitors 1a, 1b, and 2a as slow enzyme binders. Thus, recombinant α-amylase was incubated with ABPs 1c, 2b, or 2c at two quite high concentrations (100 μM or 10 μM, 1 h, 37 °C, pH 7). As shown in Figure 4A, HSA was effectively labeled by epoxide-based ABP 1c, while the labeling potency of aziridine-based ABPs 2b and 2c was dramatically reduced, and only very weak bands were observed even at 100 μM probe concentrations. In accordance with that of kinetic studies, the epoxide inhibitor 1b is much more potent than aziridine inhibitor 2a. This observation is supported by the X-ray structure analysis of inhibitor–enzyme complexes, which indicates that interactions between the −3 subsite in α-amylase active sites and the O4′ substituent may contribute to the initial binding of 1b and the resulting increased inhibition potency while the alkylation of aziridine warhead in 2a is not preferred during enzyme binding.

Activity-Based Protein Profiling of Retaining α-Amylases in Complex Biological Samples. As the next research objective, we attempted to visualize α-amylases in concentrated human saliva and lysates from mouse pancreas and salivary gland with ABP 1c. As shown in Figure 4B, ABP 1c labeled a distinct band at ∼57 kDa, corresponding to the molecular weight of HSA. The same band was also observed in mouse pancreas lysates where significant labeling appeared at 25 μM (2 h, 37 °C, pH 7), while at higher probe concentrations background fluorescence was observed. Interestingly, labeling in mouse salivary gland lysates with 1c showed two clear bands, not only the one at ∼57 kDa but also a slightly stronger band at ∼70 kDa. Next, the pH dependence of labeling was determined (Figure 4C). ABP 1c exhibits a similar pH-dependent activity toward α-amylase (at the time unknown ∼57 kDa band) in these three biological samples, and the optimal pH for labeling is determined at 5.0, different from the reported neutral pH optimum in HPA21 and HSA activity. Of note, in mouse salivary gland lysates, the band at ∼70 kDa only appeared following labeling at pH ranging from 6.0 to 8.0 with optimal labeling observed at pH 7.5. Additionally, the efficiency and the rate of labeling of α-amylase were further investigated under optimal pH 5.0 (Figure 4D and Figure 4E). In these three samples, α-amylase (the ∼57 kDa band) was selectively labeled by 1c in a concentration- and time-dependent manner, consistent with the irreversible inhibition mechanism one would expect for the maltose cyclophellitolos.
Having established that amylase activities could be visualized in extracts from human saliva, murine pancreas, and murine salivary glands, competitive ABPP (cABPP) experiments were performed to see whether these activities could be negated by inclusion of a nontagged inhibitor. Preincubation of biological samples with inhibitor 1d followed by labeling with Cy5 ABP 1c resulted in a decrease of fluorescent signals similar to denaturation of the samples with 2% SDS (Figure 4F). After fluorescent imaging, proteins were transferred to a polyvinylidene fluoride (PVDF) membrane for Western blot analysis with an anti-amylase antibody. The observed fluorescent bands and chemiluminescence bands match well where no inhibitor is included, with the chemiluminescence bands remaining equal in intensity where the ABP signal decreases in an inhibitor-dependent fashion, confirming that ABP 1c labeled amylase. cABPP assays were also performed with inhibitors 1a and 1b in human saliva (Figure S5). Compared with 1d, the inhibition potency of these two was reduced and only minor competition was observed with “untagged” 1a at the highest concentration applied (100 μM), further indicating that alkylation of the O4’ position of the epoxide-based inhibitor may improve its inhibition potency.

**ABPP of Fungal Secretomes.** The probes developed herein can also be applied to monitor the production of amylases by biotechnologically relevant fungi. Secretomes from the saprophytic ascomycete *Aspergillus nidulans* grown on various starches have previously been shown to contain a complex mixture of amylases, glucosidases, and oxidative enzymes.43 We performed ABPP of secretomes from a time course of *A. nidulans* strain FGSC A4 growth in minimal media supplemented with 1% wheat starch as a carbon source. Secretome samples were taken daily over a 5-day period, and the fluorescent Cy5 ABP 1c was incubated with these secretome samples to reveal a complex pattern of fluorescent bands that could first be detected starting by day 3. The intensity of amylase bands increased after day 3 with a maximum intensity at day 5 (Figure 5C).

Conventional industrial starch hydrolysis relies on enzymes that are both thermostable and acid tolerant.44,45 Both of these metrics can be measured directly from the secretome using ABPP, capturing these parameters in the native enzyme environment. Labeling of the day 5 secretome in the presence of McIlvaine buffers at pH between 3.0 and 8.0 revealed pH dependent labeling patterns (Figure 5A). The most intense band (observed at ~66 kDa) was labeled between pH 4.0 and pH 7.0, while the bands appearing at ~52 and ~48 kDa were constrained to labeling between 4.0 and 5.5 and 5.0–7.0, respectively. We next assessed the temperature-dependent labeling of the day 5 *A. nidulans* secretome at pH 5.0 and at temperatures between 25 and 55 °C (Figure 5B). Within this range the bands at ~66, ~52, and ~48 kDa all showed temperature dependent labeling, with labeling efficiency decreased above 37 °C, presumably due to denaturation of the corresponding proteins at this temperature. Conversely the bands at ~58 kDa and ~44 kDa remained present at the highest temperature tested.

We next used cABPP to show the sensitivity of enzyme labeling to both competitive and covalent inhibitors (Figure 5D,E). As mentioned above, cABPP allows for the identification of active enzyme inhibitors, without the need for purification and even if the identity of the active enzyme is unknown.46,47 Preincubation of secretomes for 30 min with either acarbose or 3a prior to labeling with ABP 1c resulted in decreased labeling of specific bands in a concentration dependent manner. Enzyme bands at ~66, ~58, ~52, and ~48 kDa were all inhibited by either acarbose or 3a, while the band at 44 kDa appeared to be insensitive to these *α*-amylase inhibitors.

**Identification of ABP Labeled Bands.** To further determine the specificity of the developed ABPs, we have analyzed the ABP-labeled proteins in human saliva sample. For this purpose, we incubated human saliva sample with biotinylated ABP 1d, a no probe control (DMSO only), or a competitor-inhibited control (first treatment with 1b). ABP

**Figure 5.** (A) Fluorescent labeling of day 5 *A. nidulans* secretome with ABP 1c at pH 3–8 after incubation for 1 h at 37 °C. (B) Temperature dependent labeling of day 5 *A. nidulans* secretome with ABP 1c after incubation at pH 5.0 for 1 h at 25–55 °C. (C) Fluorescent labeling of day 1–5 *A. nidulans* secretomes with ABP 1c at pH 5.0 after incubation for 1 h at 37 °C. (D) Competitive ABPP of day 5 *A. nidulans* secretome with acarbose. The secretome was preincubated with acarbose at varying concentrations (30 min, pH 5.0, 37 °C) prior to labeling with ABP 1c (67.5 μM, 1 h, pH 5.0, 37 °C). (E) Competitive ABPP of day 5 *A. nidulans* secretome with 3a. The secretome was preincubated with 3a at varying concentrations (30 min, pH 5.0, 37 °C) prior to labeling with ABP 1c (67.5 μM, 1 h, pH 5.0, 37 °C).
1d-labeled proteins were enriched by using magnetic streptavidin beads. After on-bead tryptic digestion, the resulting peptides were analyzed by LC–MS/MS and matched against the human UniProt database, using the Mascot search engine as previously described.48 As expected,AMY1A (P04745) was clearly abundant in the ABP 1d pulldown experiment (Table S2). Other proteins with high scores were background proteins such as enolase standard and keratin contaminations. Pretreatment of the saliva sample with inhibitor 1b caused a significant loss of AMY1A peptide abundance, and almost no AMY1A was found in the untreated control. These results demonstrate AMY1A in human saliva sample can be selectively labeled and identified via biotinylated ABP 1d.

On the basis of the known content of A. nidulans secretome, we tentatively assigned the most prominent ~66 kDa band labeled with 1c as the mature form of α-amylase AmyB (ANIA_03402); see Table S4 for list of mature α-amylase molecular masses. The two minor bands at ~52 and ~48 kDa were also tentatively assigned as AmyA (ANIA_03388) and AmyF (ANIA_0201) α-amylases, respectively. As the wheat starch grown secretome of A. nidulans only contains three α-amylases,49 the final two minor bands could not be confidently assigned. We however speculate that these are proteins that are highly abundant in the secretome.

To identify the labeled enzymes in the A. nidulans secretome, we also performed an activity-based protein pulldown. The day 5 secretome was treated with either the biotinylated ABP 1d or an equivalent volume of DMSO, and then a pulldown was performed using streptavidin beads, followed by an on-bead tryptic digest and LC–MS/MS analysis. All three amylases from the A. nidulans secretome (AmyA, AmyF, and AmyB) were detected at elevated levels in the probe 1d-treated samples relative to the negative control and total secretome, confirming our initial assignment of the major and two minor bands observed by in-gel fluorescence (Table S3). We also detected ChiB, an endochitinase, and AgdB, an α-glucosidase, both of which are highly abundant in the secretome (Table S3). The molecular weights of the detected amylases match well with the labeled bands seen from ABPP with probe 1c. Furthermore, these results suggest the identities of the minor bands seen at 44 and 58 kDa may belong respectively to ChiB and AgdB, the former, which is proteolytically processed from its 108 kDa form to a heterodimer with the catalytic protomer, having a 58 kDa molecular weight.49

**CONCLUSION**

We have synthesized a panel of maltobiose-configured epicyclopellitol derivatives as mechanism-based covalent inhibitors and ABPs for retaining α-amylases. Kinetic studies of the inhibition of Taka-amylase revealed that the cyclosulfate warhead (3a) is the most potent, compared with its epoxide and aziridine counterparts (1a and 2a). As well, alkylation of O4’ of the nonreducing end sugar in 1a led to compound 1b that inhibits α-amylase up to 10-fold more potently than the parent compound. Compound conformations can strongly influence the inhibitory potencies and selectivities of cyclopellitol analogues. Our X-ray studies have shown that both epoxide and cyclosulfate-based inhibitors bind to the active site nucleophilic residue of Taka-amylase in a τ-C1 chair conformation, while the structure of aziridine 2a complex was found in an unprecedented E3 conformation, likely due to the presence of the aziridine alkyl-chain, which might account for its lower potency. The inability of fluorescent ABPs 2b and 2c to modify recombinant human saliva α-amylase further indicated that substituted aziridines are not accepted by the tested amylases. In contrast, epoxide-based ABP 1c selectively labels α-amylases in human saliva and mice tissue in a concentration- and time-dependent manner, with optimum labeling at pH 5.0. In addition, it can also effectively detect α-amylases in fungal secretomes and allow easy readout of pH and temperature dependence and susceptibility to inhibitors. Looking ahead, we speculate that installation of reporter entities at O4’ of the nonreducing end sugar of cyclosulfate-based inhibitor 3a would yield more potent ABPs based on kinetic and crystallographic studies. In conclusion, our maltobiose epicyclopellitol ABPs allow activity-based profiling of α-amylases in complex biological samples and may find use in the discovery of new and effective human amylase inhibitors that may have potential as therapeutic reagents for the treatment of type 2 diabetes and in the discovery of new microbial amylases with potentially advantageous properties for biotechnological application.

Author Contributions
Y.C. and Z.A. contributed equally to this paper.

Notes
The authors declare no competing financial interest.

ACKNOWLEDGMENTS
We thank the China Scholarship Council (CSC, Ph.D. Grant to Y.C.), the Royal Society (Ken Murray Research Professorship to G.J.D.), and the Biotechnology and Biological Sciences Research Council (BBSRC) (Grant BB/R001162/1 to G.J.D. and Z.A.). We also thank the Novo Nordisk Foundation Postdoc grant within the Biotechnology-Based Synthesis and Production Research program (Grant NNF17OC0025642). We thank the Diamond Light Source for access to beamlines i04 and i03 (Proposal Numbers mx-18598-21 and mx-18598-25) that contributed to the results presented here and Johan Turkenburg and Sam Hart for coordinating data collection.
