Abstract

We present two cases of respiratory insufficiency due to left lung collapse secondary to massive pericardial effusion. Both patients had pericardial effusion due to their underlying disease. Radioimaging showed compression of the left bronchus. Patients got symptomatic relief after pericardiocentesis. Follow-up imaging showed expansion of the lung.

Keywords: Lung collapse, pericardial effusion, pericardiocentesis

INTRODUCTION

Obstruction of bronchus internally or externally can cause lung collapse. Rapidly developing lung collapse causes pain, dyspnea, and cyanosis. Symptoms may be mild or absent if collapse develops slowly. Slowly developing pericardial effusion is often asymptomatic.

Literature search did not show cases of lung collapse due to pressure of pericardial effusion in adults. The bronchus in adults is more cartilaginous and does not collapse easily.

We present two cases that developed left lung collapse due to massive pericardial effusion. The first patient had long-standing hypothyroidism with noncompliance to treatment. The other patient had hereditary hemorrhagic telangiectasia (HHT) and liver cirrhosis. Radioimaging and electrocardiography (ECHO) confirmed diagnosis. Pericardiocentesis improved the clinical and radiological picture.

CASE REPORTS

Case 1

A 42-year-old female with 8-year history of hypothyroidism, noncompliant to medications presented to the emergency department with shortness of breath and increased daytime somnolence.

She was afebrile, drowsy, tachypneic, and using accessory muscles of breathing. Heart rate and blood pressure was 68/112/60 mmHg respectively with room air saturation of 74%. Systemic examination showed decreased chest wall movement and absent air entry on left side. There was no jugular venous distension, pulses paradoxicus, or pericardial rub.

Electrocardiogram (ECG) showed sinus rhythm and low voltage complexes. Chest X-ray (CXR) revealed white out of left side [Figure 1]. Laboratory investigation revealed the following: arterial blood gas showed PaCO₂ - 76 mmHg, PaO₂ - 58 mmHg and pH - 7.20, hemoglobin 6.2 g/dl, white cell count – 5.6 x 10⁹/l, sodium - 122 mmol/L; potassium 4.6 mmol/L, TSH - 212 mIU/L (Normal: 0.35–5 mIU/L).

Noninvasive ventilation (NIV) was initiated with BiPAP mode (IPAP/EPAP-12/6, Fio₂ 40%) to support respiration. Computerized tomogram (CT) scan showed a large pericardial effusion measuring 3.5 cm thickness compressing left main bronchus causing almost complete collapse of the left lung [Figure 2]. Echocardiography (ECHO) confirmed large pericardial effusion with no signs of tamponade.

As the patient did not improve with NIV, decision was made to perform pericardiocentesis to relieve compression of left lung and 112/60 mmHg respectively with room air saturation of 74%. Systemic examination showed decreased chest wall movement and absent air entry on left side. There was no jugular venous distension, pulses paradoxicus, or pericardial rub.

bronchus. Five hundred milliliter of clear pericardial fluid was drained under ECHO using pigtail catheter. Eight hundred milliliter was drained over the next 24 h. The patient got immediate symptomatic relief. Repeat CXR showed lung expansion [Figure 3].

She was successfully weaned from NIV in the next few hours and discharged from the Intensive Care Unit within 24 h with thyroid supplementation.

**Case 2**

A 54-year-old male known case of HTT, chronic hepatitis B, and chronic anemia was admitted with bleeding per rectum.

On examination, he was conscious, oriented, emaciated, and pale. Clinical examination revealed decreased air entry on left side, muffled heart sounds, and abdominal distension with ascites. He was hemodynamically stable.

Investigations revealed hemoglobin – 1.4 g/dl, platelets – 224 x 10⁹/l, WBC – 4.6 x 10⁹/l, INR – 1.25, sodium – 136 mmol/L, potassium – 4.4 mmol/L, serum creatinine – 99 μmol/l, ECG – sinus rhythm and low voltage complexes.

CXR revealed increased cardiac shadow with loss of left lung volume [Figure 4].

Chest CT demonstrated large pericardial effusion compressing left bronchus causing collapse of the left lung [Figure 5]. Echocardiography showed massive pericardial effusion measuring $5.4 \times 5.1 \times 4.3$ with right atrium diastolic collapse.

Pericardiocentesis was performed to relieve compressing effect of effusion on heart and lung. Under echocardiography guidance, 800 ml of fluid drained. 3–3.5 L of fluid was daily drained over the next few days. Since repeat ECHO showed persistent pericardial effusion, the patient underwent left pleuropericardial window. The subsequent radiographs showed expansion of the left lung [Figures 6 and 7].

**DISCUSSION**

The heart is enclosed in a fibro serous sac-pericardium and contains about 50 ml of serous fluid. Pericardial effusion can be due to variety of causes.
Congestive cardiac failure, nephrotic syndrome, cirrhosis, and protein malnutrition cause serous effusion. Bloody effusions are common in acute myocardial infarction, malignancies, postcardiac surgery, anticoagulant use, and chronic renal disease. Injury to thoracic duct results in chylous effusion. Tuberculosis, Coxsackie B virus, and bacterial infections cause effusion.

Clinical presentation depends on the etiology and rate of fluid collection. Rapid accumulation leads to dramatic symptoms of cardiac tamponade. Slowly accumulating pericardial fluid allows large effusions to collect over time before a significant increase in pressure occurs to cause symptoms. Often, these effusions are drained to relieve cardiac tamponade.

About 3%–6% of patients with hypothyroidism develop pericardial effusion. It is commonly seen if the disease is not adequately controlled with medications. Increased systemic capillary permeability, disturbances in electrolytes, and lipid metabolism are the proposed mechanisms. These patients are often asymptomatic, and effusion is discovered on routine investigations. Treatment is thyroxin supplementation, and only a small number of patients who present with cardiac tamponade require pericardiocentesis. First patient presented with a large pericardial effusion without cardiac tamponade but rather an unusual presentation of lung collapse due to compression of left bronchus which required pericardiocentesis.

HHT is an autosomal dominant-inherited disorder characterized by vascular malformations predominantly in the brain, liver, and lungs. Patients present with hemorrhages causing anemia and organ-related symptoms such as stroke, pulmonary, and portal hypertension. Our patient had vascular malformations involving the entire gastrointestinal tract and liver cirrhosis causing repeated GI bleed, portal hypertension, and ascites. He presented with breathlessness that was initially attributed to anemia. Persistence of symptoms after correction of anemia, evidence of cardiomegaly, and left-sided haziness on CXR led to echocardiography and CT scan examination that showed significant pericardial effusion. There was no pleural effusion. Hemorrhagic pericardial effusion has been described in patients with HHT. Our case did not have a hemorrhagic effusion. Cirrhosis and associated hypoalbuminemia could have resulted in an effusion. Though the echocardiography showed right atrial collapse, there was no hemodynamic instability suggesting tamponade. Chest CT revealed compression of left bronchus with collapse.

In both cases, pericardiocentesis was done to relieve compression on left bronchus. Both patients showed clinical and radiological evidence of improvement after pericardiocentesis.

The heart is situated more in the left side of thorax in the middle mediastinum. Left main bronchus is twice the length of right bronchus and more horizontally placed. Its anatomical relation to heart in the mediastinum makes it more prone to compression by the enlarging pericardial effusion. There are
reports of left bronchus compression by enlarged left atrium, pulmonary artery, and lymph nodes in children.\[^9,10\]

Literature search did not show reports of pericardial effusion causing lung collapse in adults.

Left lung expanded completely in the first case and partially in the second patient who required pleuropericardial window creation.

**Conclusion**

Long-standing massive pericardial effusion can cause compression of bronchus leading to lung collapse in adults. Anatomical location of the left main bronchus makes it more susceptible to collapse. Pericardiocentesis can give symptomatic relief to patients with respiratory insufficiency with radiological evidence of compression.

**Declaration of patient consent**

The authors certify that they have obtained all appropriate patient consent forms. In the form the patient(s) has/have given his/her/their consent for his/her/their images and other clinical information to be reported in the journal. The patients understand that their names and initials will not be published and due efforts will be made to conceal their identity, but anonymity cannot be guaranteed.
