ABSTRACT
Congenital diaphragmatic hernia (CDH) occurs due to incomplete muscularization of the diaphragm. While majority of these are diagnosed either antenatally or in the immediate new-born period in view of respiratory distress, a few may remain undiagnosed beyond neonatal period as they are asymptomatic or minimally symptomatic. We report two such cases who presented with respiratory distress and were diagnosed to have late presenting CDH. An eight-year-old male child with weight of 12 kg presented with intermittent fever and cough for one-month, abdominal distension, and occasional bilious vomiting for 15 days and respiratory distress for 2 days. Ultrasonography of the chest revealed herniation of abdominal contents in the left chest cavity and sub-acute intestinal obstruction. He underwent surgery but succumbed to his illness. A 2-year-old female child came to the emergency department with fever, cough for 20 days and respiratory distress for 4 days. X-ray chest showed left large air-fluid filled cavity in the left lung. She underwent emergency laparotomy and a defect in the left hemi-diaphragm with herniation of stomach was noted. The hernia contents were reduced, and diaphragmatic defect closed. Post operatively she recovered well and was discharged after 7 days with full recovery.

Introduction
Congenital diaphragmatic hernia (CDH) occurs in approximately 1 in every 2000 to 4000 newborns.1 The most common defect is on left side (80-85%) posterolaterally.2 More than 90% of these are either diagnosed antenatally or in the immediate new-born period in view of respiratory distress and are associated with significant mortality.3 However about a few cases may present beyond neonatal period. Late presenting CDH has been defined as CDH diagnosed after the neonatal period which may have been asymptomatic or only few symptoms in neonatal period and picked up on routine X-ray examination of chest beyond the neonatal period.2,4 The late presenting CDH is reported to have incidence of as high as 5-45.5 % of all cases of CDH.2,4 Late presenting CDH is relatively rare, often misdiagnosed, and hence gets delayed treatment. While the neonatal CDH carries high morbidity and mortality rates, the late-presenting CDH carries favourable prognosis if diagnosed early. We report case series of two cases presenting to our institute with this disorder and their outcome.

Case 1
An eight-year-old male child presented to the emergency room with intermittent fever and cough for one-month,
Case 2

A 2-year-old female child came to the emergency department with fever, cough for 20 days and respiratory distress for 4 days. She was asymptomatic before this episode. On examination she had significant respiratory distress with a heart rate: 130/min and respiratory rate of 50/min. Her weight was 9kg (<3rd centile). On respiratory system examination, air entry was reduced on the left side with shift of mediastinum to the right. Initial X-ray chest showed left large air-fluid filled cavity for which chest tube was put. Repeat chest radiograph with nasogastric tube was done which showed tip of the naso-gastric tube in the left hemithorax clinching the diagnosis of CDH (Figure 3).

She underwent emergency laparotomy; herniation of stomach was noted through a defect in the left hemidiaphragm and reduction of same and closure of the defect was done. She was discharged after 7 days with full recovery.

Discussion

CDH results from incomplete closure of the normal pleuropertitoneal canal during the fetal development. They are classified based on the herniation time, the severity of pulmonary hypoplasia, survival, and the presence of late pulmonary sequelae. Type 1 refers to cases in which the herniation develops in the early period of rapid bronchial division. Hence it results in unilateral pulmonary hypoplasia, and potential pulmonary hypertension. Type 3 refers to cases in which the herniation has occurred during either late gestation or early neonatal period. In them herniation might present at birth with mild respiratory distress. Pulmonary hypoplasia is minimal or absent and most of them survive with no detectable respiratory problems. In the type 4, the herniation occurs after the neonatal period and such patients have no pulmonary hypoplasia and survive with no respiratory problems. Especially in type 4 patients there may be no herniation until an episode of increased abdominal pressure causes herniation to develop. Both our patients had type 4 herniation as they had no pulmonary hypoplasia.

CDH may also be associated with other secondary abnormalities or congenital abnormalities. The secondary abnormalities commonly associated are malrotation of intestines and pulmonary hypoplasia. Cardiac abnormalities have been reported to be associated in such patients.

Diagnosis is frequently made by chest X-ray, but it can mimic pneumothorax, cavity with air-fluid level, pleural effusion, or eventration of diaphragm, thereby leading to misdiagnosis. In such cases chest CT scan leads to confirmatory diagnosis and prevents delay in treatment.

As soon as the diagnosis is confirmed early surgical intervention should be sought to prevent unnecessary...
complications. Late presenting CDH has more favourable prognosis due to absence of pulmonary hypoplasia. Acute gastric volvulus associated with CDH is extremely rare but life-threatening complication. It is associated with elongation or absence of 2 of the 4 ligaments of stomach which are attached to the left diaphragm. Any increased abdominal pressure in such cases may lead to fatal consequences like gastric strangulation, ischaemia, perforation, pancreatitis, peritonitis, shock, and death with a mortality of 80%. Late presenting CDH with gastric volvulus is often misdiagnosed as pneumonia with cavity formation, tension pneumothorax, empyema or pneumatocele. Unfortunately, this many times leads to iatrogenic error of inserting chest tube and causing life threatening complications. In our second patient, chest tube was inserted but it did not lead to any life-threatening complications. Inappropriate tube insertion may lead to damage to intrathoracic abdominal viscera. There is also risk of spillage of gastric and abdominal contents into the mediastinum leading to mediastinitis or damage to blood vessels leading to haemorrhage. If CDH is suspected on plain radiograph, it can be easily diagnosed by placing a nasogastric tube and repeating the chest X-ray; in CDH the tip of the nasogastric tube can very well be seen in the thoracic cavity as was seen in our second patient. Whenever gastric volvulus is suspected surgery should not be delayed and early stomach decompression should be done to reduce the distension.

**Conclusion**

Late presenting CDH can have wide spectrum of clinical presentation and hence a high index of suspicion is required for diagnosis. Early pick up and treatment can prevent development of life-threatening complications like gastric volvulus. Early diagnosis and treatment can lead to good outcomes.
