Bacterial vaginosis is characterized as a polymicrobial dysbiosis with the loss of *Lactobacillus* spp. and growth of multiple anaerobic bacteria, including *Gardnerella*, *Prevotella* and *Atopobium* ranked as the top three most abundant. A total of nine *Gardnerella* genomospecies have been identified, yet the association between their distribution or any exact *Lactobacillus* species with BV occurrence or prognosis remains controversial. A total of 308 patients and 62 healthy women who sought annual examinations were recruited, with 130 BV patients and 41 healthy women finally included. Vaginal samples were used for microscopic examination, 16S rRNA sequencing, bacterial culture and isolation. Isolates of *Gardnerella vaginalis*, *Fannyhessae vaginae* (used to be called *Atopobium vaginae*) and *Lactobacillus iners* were used for competition tests. We found that the relative abundances of *Gardnerella*, *Prevotella* and *Atopobium* were elevated in BV patients compared to healthy people (p<0.0001), yet no significant differences were found among patients with different clinical outcomes (p>0.05). Seven out of nine *Gardnerella* genomospecies were present in both BV patients and healthy women, and the relative abundances of all detected genomospecies were higher in BV patients (p<0.05). Cured patients possessed higher GS03 than intermediate and failed patients (p=0.005, 0.0337). *L. iners* was significantly higher in cured patients than in the other two groups (p=0.0021, p<0.0001), and its ability to inhibit the growth of *G. vaginalis* and *F. vaginae* was validated. In summary, seven *Gardnerella* genomospecies were detected in Chinese BV patients, but no association of its distribution and BV occurrence or prognosis was found. The relative abundance of *L. iners* was higher in cured patients, and its antimicrobial activity against *G. vaginalis* and *F. vaginae* was validated through *in vitro* inhibition experiment. *L. iners* could become a predictive indicator of clinical outcomes of BV patients, and its antimicrobial function might be beneficial to BV patients.

**KEYWORDS**
bacterial vaginosis, *Gardnerella* genomospecies, *Lactobacillus iners*, 16S rRNA sequencing, antimicrobial activity
Introduction

Bacterial vaginosis (BV) is the most common lower genital tract infection, affecting approximately 4.75% of reproductive-aged women internationally (Kenyon et al., 2013; Onderdonk et al., 2016; Abou Chacra et al., 2021). However, the exact etiology of BV still remains unclear. BV is characterized as a dysbiosis of the vaginal microbiome in which the Lactobacillus spp. dominant flora is lost (Abou Chacra et al., 2021), accompanied by a significant increase in anaerobic bacteria, including Gardnerella, Atopobium, Prevotella, Megaspheera, Mobiluncus and so on (Ravel et al., 2011; Muzny et al., 2018; Muzny et al., 2019; Mohankumar et al., 2022). Antibiotics such as metronidazole and clindamycin are recommended for BV treatment, and the short-term cure rate varied from 46.75%-96.20%, but above 70% of women will experience at least one episode of BV recurrence within 12 months (Bostwick et al., 2016; Munoz-Barreno et al., 2021). Recurrent episodes of BV have been demonstrated to be related to a variety of adverse outcomes in gynecology and obstetrics, such as sexually transmitted diseases, cervical cancer, pelvic inflammatory disease, infertility, and premature birth, causing a significant financial burden to the health system and society worldwide (King et al., 2011; Srinivasan et al., 2012; Ravel et al., 2021; Abou Chacra et al., 2021).

In past studies, a variety of anaerobic bacteria have been shown to be closely related to BV. Among these bacteria, Gardnerella has attracted special attention, as a series of 16S rRNA sequencing-based techniques have revealed that it could be detected in almost all BV patients, and its presence accounts for the formation of polymicrobial biofilms, which are related to refractory or recurrent BV (Jung et al., 2017; Vestby et al., 2020; Rosca et al., 2022); paradoxically, 40% of healthy women also test positive for such bacteria (Jung et al., 2017). Therefore, whether this species is the contributing pathogen for BV remains debatable (Swewbeke et al., 2014; Onderdonk et al., 2016; Morrill et al., 2020). In recent years, researchers have isolated and identified 9 genomospecies of Gardnerella through cpn60 gene typing, whole genome sequencing and other methods (Schellenberg et al., 2018; Schellenberg et al., 2017; Hill and Albert, 2019; Vaneechoutte et al., 2019; Qin and Xiao, 2022). Many investigations have focused on identifying the differences in the ability to adhere to vaginal epithelial cells, virulence and drug resistance among genomospecies and the relevance of the distribution of Gardnerella genomospecies with the occurrence, symptoms or clinical outcome of BV, but the results lack consistency (Santiago et al., 2011; Onderdonk et al., 2016; Hardy et al., 2017; Hillbert et al., 2017; Deng et al., 2018; Janulaitiene et al., 2018; Ferreira et al., 2021; Khan et al., 2021).

With respect to the normal vaginal microbiome, which is important for the homeostasis of the vaginal environment, studies have also accumulated and concluded that the loss of Lactobacillus is an essential part of the progression of BV (Abou Chacra et al., 2021). Based on 16S rRNA sequencing of women across countries and ethnic groups, it is generally accepted that L. crispatus, L. iners, L. gasseri and L. jensenii are the four most commonly detected Lactobacillus species in the vaginal microbiome (Ravel et al., 2011). Former studies have explored the probiotic effect of different Lactobacillus spp. against different pathogens, with L. crispatus considered to be the most important species contributing to reproductive health and the combination of L. gasseri, L. jensenii and L. acidophilus might manifest protective effect against dysbiosis of vaginal microbiota (Pacha-Herrera et al., 2022). However, the true role L. iners playing in BV progression and prognosis or the restoration of normal vaginal flora remains debatable (Vaneechoutte, 2017; Abou Chacra et al., 2021). Thus, in our study, we profiled the vaginal microbiome in healthy women and BV patients before and after antibiotic treatments and explored the potential contributions of Gardnerella and Lactobacillus to the treatment outcome of BV at the genomospecies or species level.

Materials and methods

Cohort recruitment

A total of 308 premenopausal (18-50), nonpregnant women who came to Peking University First Hospital with major complaints about vulvovaginal discomfort and/or abnormal vaginal discharge and 62 women who underwent annual physical examinations from August 2020 to August 2021 were recruited for our study and a written form of informed consent was collected, approved and supervised by The Ethics Committee of Peking University First Hospital. All participants underwent blood tests, urine tests and cervicovaginal microscopic or PCR tests to rule out infections of HIV, HPV, HSV-2, syphilis, Chlamydia trachomatis, Neisseria gonorrhoeae, vulvovaginal candidiasis, Trichomonas vaginalis, Ureaplasma urealyticum, M. hominis, urinary tract infections and internal diseases, such as hypertension, diabetes, and hyperlipidemia. Exclusion criteria included pregnancy, diagnosis of any diseases mentioned above, multiple sex partners, history of any intrauterine operations such as hysteroscopy or implantation of intrauterine devices. Patients who were currently in the menstrual period or took oral contraception, any antibiotics whether orally, intravenously or vaginally applied within 30 days or engaged in sexual intercourse within 7 days ahead of sample collection were also excluded from this study. Information of menstrual cycle, last menstruation and reproductive history was also collected by the time of sample collection.

Sample collection

Three vaginal microbiome samples were collected from the same position in the upper 1/3 of the anterior vaginal wall with
vaginal swabs (Becton, Dickinson and Company) during inspection. The first swab was used for DNA extraction and sequencing and immediately stored at -80°C. The second swab was used for Gram staining, microscopic examination and evaluation of biological parameters. The last swab was used for bacterial culture, isolation and purification. The studies involving human participants were reviewed and approved by the Ethics Committee of Peking University First Hospital. All participants signed informed consent in written form for the publication of any potentially identifiable images or data included in this article and agreed to be involved in our follow-up voluntarily.

Diagnostic procedures and treatment

The presence of BV is diagnosed by the Gram stain-based Nugent score according to Nugent et al. (Nugent et al., 1991) (a score of 0-3 is considered to be normal for BV, 4-6 intermediate status, and 7-10 BV) and Amsel criteria according to Amsel et al (Amsel R Fau - Totten et al., 1983) (BV is diagnosed when at least three of the following criteria are fulfilled: Homogenous, thin, grayish-white vaginal discharge that smoothly coats the vaginal wall, vaginal pH>4.5, release of fishy odor when 10% potassium hydroxide is added, and/or over 20% clue cells present on one saline wet mount). Two experienced technicians were involved in the microscopic examination separately and blinded to each other to ensure the authenticity of the diagnosis. Patients who were diagnosed with BV were prescribed topical 5% metronidazole gel to ensure the authenticity of the diagnosis. Patients who were diagnosed with BV were prescribed topical 5% metronidazole gel for 5 days. All patients were asked to visit their gynecologist again within one week after completion of their treatment. Another two vaginal swabs were collected following the procedures above. The same diagnostic procedures mentioned above were repeated to confirm the patients’ clinical outcomes: cured (Nugent 0-3), intermediate (Nugent 4-6) and failed (Nugent 7-10).

Genomic DNA isolation from vaginal samples

The vaginal swab and scraped samples were vortexed and centrifuged for 10 min at 10,000 g to collect the bacterial cells, and the supernatant was discarded. All genomic DNA extractions were performed by using the DNeasy® Power Soil® Pro Kit (Qiagen) following the manufacturer’s instructions.

16S rRNA sequencing

A 16S rRNA gene fragment comprising the V3 and V4 hypervariable regions was amplified by using the V3 forward primer 5’-CCTACGGGNGGCASCAG-3’ and the V4 reverse primer 5’-GACTACNVGGGTATCTAATCC-3’. The amplified products were checked and analyzed on a 2% agarose gel. Sequencing was performed using a 250-bp paired-end sequencing protocol on the Illumina NovaSeq6000 platform. Sequence analysis was performed following a previous study (Falony et al., 2016). The sequences were merged using the FLASH program (Magoc and Salzberg, 2011) and subjected to quality filtering using the FASTX-Toolkit (http://hannonlab.cshl.edu/fastx_toolkit/). Chimeras were excluded using the UCHIME command and the ‘GOLD’ database (Edgar et al., 2011). After random rarefaction of microbiome sizes to 6555 reads, the taxonomic assignment of reads was determined by RDP classifier (Wang, 2007) to generate the composition matrices at the level of the phylum to the genus (Wang et al., 2007). The 6,555 rarefied reads were also blasted against the 16s rRNA sequences of established Gardnerella genospecies and Lactobacillus species (including L. crispatus, L. iners, L. jensenii and L. gasseri) to identify the genospecies Gardnerella and Lactobacillus. The 16S rRNA sequences of Gardnerella and Lactobacillus species in NCBI were collected (Supplementary Table 1) were distinguishable at the species level (Supplementary Figure 1) and were used to build the species level database of Gardnerella and Lactobacillus. The 6,555 rarefied reads were classified using the BLASTn algorithm against the species level database to identify the species of Gardnerella and Lactobacillus with identity threshold of >99%.

Bacterial isolation and culture conditions

Vaginal swabs were immediately inoculated onto Colombia blood agar, baked sheep blood agar with kanamycin and vancomycin and MRS broth (BD Difco®) supplemented with IsoVitale XTM Enrichment (BD BBLTM; 2% v/v) and L-Cys (augmented by L-Gln, with a final concentration of 1.1 mM). All broths mentioned above were securely stored at 4°C until used. The broths were placed into an anaerobic environment at 37°C using an AS-580 anaerobic chamber (anaerobic system) with an atmosphere of 5% carbon dioxide, 5% hydrogen, and 90% nitrogen (AirgasO) for 24-48 hours. All bacterial colonies from all broths were picked out, purified and identified through 16S sequencing. G. vaginalis, F. vaginae and L. iners were tittered and maintained on Colombia blood agar.

Antimicrobial activity evaluation

Purified Gardnerella vaginalis and Fannyhessae vaginae (used to be classified into Atopohium vaginae) strains were spread onto Colombia blood agar and coated on all boards after activation. Agar containing purchased L. johnsonii strains was used as positive control and agar containing purified water was used as negative control. Purchased L. johnsonii was safely stored in Microbank tubes (ProLab) at -80°C and fully activated before experiment. Agars containing isolated L. iners, purchased
L. johnsonii or water were placed onto broth coated with either G. vaginalis (GS01) or F. vaginae and cultured under the anaerobic conditions mentioned above. Parallel tests for L. johnsonii and L. iners were run to ensure the validity of our results. The diameter of the inhibition zone was measured after culturing for 24-48 h.

**Statistical analysis**

Statistical analysis of bacterial taxonomic identification was performed using R v4.1.1 software. The vegan package was used to analyses the α-diversity and conduct permutational multivariate analysis of variance (PERMANOVA) (Somerfield et al., 2021) followed in case of significant effects by a constrained canonical analysis of principal coordinates (Anderson, 2003). The Wilcoxon test and Kruskal-Wallis test in the ggpubr package were used to measure the difference in richness, α-diversity and abundance.

**Results**

**Cohort description**

Of the 370 participants we recruited, 130 BV patients and 41 healthy women were ultimately included in our study. The clinical information of all participants is shown in Table 1. After a standard 5-day metronidazole treatment, patients were divided into three groups according to their clinical outcome: 61 patients were cured (46.9%, group cured), 36 patients turned to intermediate BV (27.7%, group intermediate), and 33 patients still had BV (25.4%, group failed). There was no significant difference in age between healthy women and BV patients (38.03 vs. 37.19, p=0.4764, Kruskal-Wallis test). However, statistically significant differences could be seen in both Nugent score (0.58 vs. 7.88, p<0.0001, Kruskal-Wallis test) and pH (4.21 vs. 5.02, p<0.0001, Kruskal-Wallis test) between the two groups. Moreover, no difference was found in reproductive history or proportion of participants in any menstrual period between healthy participants and BV patients (Table 1). Furthermore, we analyzed the differences in Nugent score and vaginal pH among the three groups before treatment, and no significant differences were found.

**BV patients have higher Gardnerella, Prevotella and Atopobium**

We analyzed all vaginal microbiota through 16S rRNA sequencing (Figure 1). The results reveal that Lactobacillus spp. are the most dominant species in healthy women (78.95%), while 16 (39%) are L. crispatus dominant and 14 are L. iners dominant (34%). The average relative abundance of L. crispatus among those who were L. crispatus dominant was 71.77%, while average L. iners abundance was 81.27% when L. iners was dominant. In contrast, BV-related bacterial species are the most prevalent taxa in BV patients before taking any medications: Gardnerella spp. (35.61%) Prevotella (11.66%) and Atopobium (10.69%) were among the top three highest relative abundances in BV patients (Table 2). In terms of relative abundance before treatment, all three bacteria were statistically higher than those in healthy women (p<0.0001, Kruskal-Wallis test), while the relative abundance of each bacterium was similar among groups before the application of metronidazole and not statistically significant (p>0.99, Kruskal-Wallis test) (Figure 2).

BV, bacterial vaginosis; STI, sexually transmitted infections.
*Other STI include HIV, HPV, HSV-2, syphilis, Chlamydia trachomatis, Nesseria gonorrhoeae, vulvovaginal candidiasis, Trichomonas vaginalis, Ureaplasma urealyticum, M. hominis, and urinary tract infections. Only statistically significant P value is manifested in the table. Kruskal-Wallis test was used for inter-group comparison.
We then analyzed the vaginal microbiome in BV patients after metronidazole treatment and found significant differences in microbiome composition among patients in different clinical outcome groups. In cured patients (group cured), the relative abundance of all three BV-associated bacteria significantly decreased (p<0.0001, Wilcoxon test), yet the relative abundance of Gardnerella spp. was still higher than that in the healthy cohort (p<0.0001, Wilcoxon test). The relative abundance of both *Atopobium* and *Prevotella* decreased posttreatment in the intermediate group (group intermediate, p=0.0103, p<0.0001, Wilcoxon test), but the abundance of Gardnerella spp. did not change significantly (p=0.0946, Wilcoxon test). In contrast to the two groups with improvement, no significant decrease in any bacteria was detected in patients without improvement (failed group). Intergroup comparison shows that patients in the cured group had a lower relative abundance of Gardnerella spp., *Atopobium* and *Prevotella* than the failed group (p=0.0009, p<0.0001, p<0.0001, Kruskal-Wallis test) and a lower relative abundance of *Atopobium* and *Prevotella* than the intermediate group.
TABLE 2  Relative abundance of top 10 most abundant bacteria at genus level.

**Cured patients possessed higher GS03 pretreatment**

Since former studies have recognized nine different Gardnerella genomospecies via whole genome sequencing, only seven genomospecies have been detected in our specimen, namely, GS01, GS02, GS03, GS05, GS07, GS08 and GS09, with decreasing abundance. Each detected Gardnerella genomospecies was increased in BV patients compared to healthy women (<0.05), yet no statistical differences were noticed among groups with different clinical outcomes pretreatment. After metronidazole treatment, α-diversity was reduced in group cured and significantly higher than group intermediate and group failed, but was still significantly higher compared to healthy women. No statistical changes of α-diversity were noticed in either group intermediate or group failed after treatment. Moreover, no statistical differences were shown between group intermediate and group failed post-treatment. (p=0.0002, p=0.0038, Kruskal-Wallis test). Meanwhile, the intermediate group contained a lower relative abundance of Atopobium and Prevotella than the failed group (p=0.0022, p=0.0254, Kruskal-Wallis test), but the relative abundance of Gardnerella spp. showed no significant differences between the cured and intermediate groups or between the intermediate and failed groups (Figure 2).

Furthermore, we analyzed the α-diversity (Shannon index and Chaol index) in participants’ vaginal microbiota (Supplementary Figure 3). We found that, α-diversity in all BV patients was significantly higher compared to healthy women (p<0.05), yet no statistical differences were noticed among groups with different clinical outcomes pretreatment. After metronidazole treatment, α-diversity was reduced in group cured and significantly higher than group intermediate and group failed, but was still significantly higher compared to healthy women. No statistical changes of α-diversity were noticed in either group intermediate or group failed after treatment. Moreover, no statistical differences were shown between group intermediate and group failed post-treatment.
FIGURE 2
Comparison of Gardnerella, Prevotella and Atopobium abundance in different groups. Intergroup comparison of Gardnerella (A), Prevotella (B) and Atopobium (C) relative abundance. Only statistically significant P value that has clinical meaning is marked in the graph. Significance is exhibited as: *: p<0.05; **: p<0.01; ***: p<0.001; ****: p<0.0001; Wilcoxon test for pairwise comparison between pre- and posttreatment and Kruskal-Wallis test for comparisons among different groups.
TABLE 3 Relative abundance of each *Gardnerella* genomospecies in each group.

BV, bacterial vaginosis; GS, genomospecies.

* "Group Cured" was defined as patients whose Nugent score were lowered to 0-3 after metronidazole treatment.

* "Group Intermediate" was defined as patients whose Nugent score were changed to 4-6 after metronidazole treatment.

* "Group Failed" was defined as patients whose Nugent score remained at 7-10 after metronidazole treatment.

* Wilcoxon test was used for comparison between these two groups.
the growth of GS01 and F. vaginae in the in vitro coculture system, yet system of negative control showed no sign of antimicrobial abilities. (Supplementary Figure 4).

Discussions

Our study shows that L. iners (30.33%), L. crispatus (29.21%) and Gardnerella (7.12%) ranked the top three most prevalent bacteria in healthy Chinese women, with Gardnerella (37.12%), Prevotella (10.73%) and Atopobium (8.72%) ranked as the top three in BV patients, but no such correlation between the relative abundance of Gardnerella, Atopobium or Prevotella and clinical outcomes was found. Interestingly, even though the amount of healthy individuals dominant by L. crispatus was slightly higher than those dominant by L. iners (16 vs 14), we noticed that the average relative abundance of L. crispatus was even mildly lower than L. iners (29.21% vs 30.33%). This was due to the average abundance of dominant Lactobacillus species was different. It seems that when L. iners is the dominant species in vaginal flora, it occupies more ecological niche than L. crispatus. Our study also showed that BV patients had higher richness and diversity compared to healthy women pretreatment which is in consistence with former studies. The reduction of diversity in group cured after treatment infers the success of treatment, yet the richness is still significantly higher than healthy women indicates that further therapeutic procedures might be required to fully restore the normal vaginal microbiota.

Former studies have demonstrated that different genospecies of Gardnerella spp. manifest diverse characteristics such as virulent factors, adherent abilities, antibiotics resistance, etc. Although lacking explicit conclusions, studies based on cohorts from other regions and ethnicities, utilizing the concept of “Gardnerella clades” based on cpn60 sequencing reported that different structures of the Gardnerella clades are related to BV, as certain genospecies being more abundant or positive in BV patients, while others are not (Numanovic et al., 2008; Vodstrcil et al., 2017). In our study, we brought former studies to a further level as we analyzed Gardnerella genospecies which were classified by whole-genome sequencing. We detected seven out of nine genospecies in Chinese women, with the absence of GS04 and GS06 and all detected genospecies were presented in both BV patients and healthy people. Furthermore, GS01, GS02,
TABLE 4 Relative abundance of four species in each group.

| Species          | Healthy BV patients | P-value | Posttreatment P-value | Posttreatment P-value |
|------------------|---------------------|---------|-----------------------|-----------------------|
| L. crispatus     | 29.21 (18.01-40.41) | >0.05   | 0.08 (0.06-0.11)      | <.0001                |

BV, bacterial vaginosis.

At the same time, our study noticed that patients with more L. iners before treatment might have a better clinical outcome. This is a notable finding, as it indicates that L. iners may be an innovative indicator for BV clinical outcomes, in contrast to previous findings that it might be an opportunistic pathogen (Lee et al., 2020). Different from other Lactobacillus species mentioned in this article, L. iners shows unique metabolic and genomic characteristics, and its protective function is questionable compared to other Lactobacilli (France et al., 2016; France et al., 2020; Bloom et al., 2022; France M. T. et al., 2022). Its production of hydrogen peroxide and D-lactic acid is lower, and the inerolysin it secretes is thought to be a cholesterol-dependent cytotoxin that is homogenous to vaginolysin and expressed by several BV-associated bacteria (Zhou et al., 2010; Pleckaityte, 2019; Ragaliauskas et al., 2019; Zheng et al., 2021). It has been acknowledged that metronidazole instantly reduces the load of vaginal microbiota, and L. iners becomes the dominant species (Lehtoranta et al., 2020; Verwijs et al., 2020; Armstrong et al., 2022), but this kind of structure is unstable and has the potential to lead to BV recurrence (France M. T. et al., 2022). Although lacking consistent conclusions, L. iners is considered to be a “foe” instead of a “friend” (Hill and Albert, 2020; Zheng et al., 2021; Novak et al., 2022). However, our study proposed a novel point of view, as we found that the cured patients’ microbiome had more L. iners. Our in vitro experiments also validated the inhibitory effect of L. iners against G. vaginalis and F. vaginae. We assume that when L. and GS03 ranked the top three most prevalent and GS08 the least in both BV patients and healthy people. No genomospecies are thought to be specifically related to BV, as the relative abundance of all genomospecies is significantly higher in BV patients than in healthy women.

A previous study reported an association between a high abundance of certain Gardnerella genomospecies or a combination of several genomospecies with BV clinical outcomes (Harwich et al., 2010; Hilbert et al., 2017; Faught and Reyes, 2019; Hill and Albert, 2019; Shipitsyna et al., 2019), and coinfection of GS03 and GS04 was thought to be related to negative clinical outcomes based on a cohort of recurrent BV patients (Turner et al., 2021; Qin and Xiao, 2022). In contrary to former studies, our study found that the relative abundance of GS03 was even higher in cured patients. However, whether GS03 relative abundance is associated with better clinical outcomes might remain controversial, as in our study, GS01 is the most prevalent Gardnerella genomospecies and former studies have shown that GS01 is less resistant to metronidazole compared to GS03 (35% vs 100%). GS03 only made up 3.84% of the whole bacterial taxa which was approximately 1/5 of the most abundant genomospecies GS01(14.7%) and it’s difficult to determine whether this small amount of GS03 is able to shift the clinical outcomes of BV patients. Therefore, we propose that GS01 instead of GS03 might be the most important genomospecies affecting BV clinical outcomes.
*L. iners* is higher at the time of treatment, its antimicrobial abilities might facilitate the therapy of BV, as it is resistant to metronidazole and able to scavenge pathogens simultaneously. Furthermore, considering that *L. iners* is capable of synthesizing L-lactic acid and a small amount of D-lactic acid (Vaneechoutte, 2017), we hypothesized that the restoration of *L. iners* after treatment might be crucial for the recovery of other *Lactobacillus* by maintaining an acidic environment and countering the growth of BV-associated bacteria.

This study is the first attempt to describe the distribution of *Gardnerella* genospecies in Chinese women to determine its relationship with the clinical outcomes of BV patients. Moreover, we also validated the inhibitory effect of *L. iners* against *G. vaginalis* and *F. vaginae* through coculture experiments. Though with limited sample size and restricted experimental conditions, our conclusion could be more general with more incorporated participants. Nonetheless, our *in vitro* test is only preliminary in explaining the correlation of *L. iners* with BV clinical outcomes. In future studies, more experiments and animal models are needed to reveal the mechanism underneath the relation between *L. iners* and BV clinical outcomes and more participants are required to better represent the *Gardnerella* genospecies distribution in China.

**Conclusion**

Our research found seven *Gardnerella* genospecies and revealed that Chinese women and cured patients possessed higher GS03 and *L. iners* pretreatment and validated the
inhibitory effect of *L. iners* against the growth of *Gardnerella vaginalis* and *Fannyhessae vaginae*. Finally, we suggest gynecologists have a better understanding of the vaginal microbiota of BV patients pretreatment to improve their overall health and that *L. iners* might become an innovative biomarker for BV treatment outcomes.

**Data availability statement**

The datasets presented in this study can be found in online repositories. The names of the repository/repositories and accession number(s) can be found below: https://nmdc.cn/resource/attachment/detail/NMDCX0000148.

**Ethics statement**

The studies involving human participants were reviewed and approved by The Ethics Committee of Peking University First Hospital (2020[083]-001). The patients/participants provided their written informed consent to participate in this study.

**Author contributions**

BX and JW designed the project. BX collected samples. RZ and JL ran the experiment procedure. All authors participated in data analysis, writing and discussing the contents of this article and approved the submitted version.

**Funding**

This present work was funded by the grants of the National Natural Science Foundation of China (81971342) and the National Key Research and Development Program of China (2021YFC2301000).
