Abstract

We describe the hybridization-expansion continuous-time quantum Monte Carlo code package “w2dynamics”, developed in Wien and Würzburg. We discuss the main features of this multi-orbital quantum impurity solver for the Anderson impurity model, dynamical mean field theory as well as its coupling to density functional theory. The w2dynamics package allows for calculating one- and two-particle quantities; it includes worm and further novel sampling schemes. Details about its download, installation, functioning and the relevant parameters are provided.

Keywords: (continuous-time) quantum Monte Carlo, Anderson impurity model, dynamical mean field theory, Green’s functions

PROGRAM SUMMARY

Program Title: w2dynamics
Licensing provisions: GNU General Public License (GPLv3)
Programming language: Python, Fortran 90, and C++11
Required dependencies: cmake (≥ 2.8.5), MPI, LAPACK, FFTW3, Python (≥ 2.4)
Optional dependencies: NFFT, pip, numpy (≥ 1.4), scipy (≥ 0.10), h5py, mpi4py, configobj

Nature of problem:
Numerically unbiased solutions of one- and two-particle propagators for quantum impurity models at finite temperature. Approximate solutions for general lattice models with strong electronic correlation.

Solution method:
Continuous-time quantum Monte Carlo in the hybridization expansion, including worm sampling, for the impurity problem. Dynamical mean field theory solver for the lattice problem.

1. Introduction

Strongly correlated electron systems exhibit a range of fascinating phenomena such as the Mott-Hubbard metal-to-insulator transition, spin- and charge-density wave states, giant magnetoresistance, and heavy fermion behavior. However even a numerical solution of correlated lattice models, not to speak of realistic materials calculations, is impossible in practice, except for very few lattice sites, because the Fock space scales exponentially with the number of lattice sites and orbitals. The single impurity Anderson model (SIAM)\textsuperscript{1} is the
rare exception of a correlated electron model that is non-trivial while a numerical solution is still feasible. For a single (or a few) orbital(s) this can be done by the numerical renormalization group (NRG),\textsuperscript{2} matrix product states (MPS),\textsuperscript{3,4,5} or, if the conduction electron bath is discretized by a few sites, by the exact diagonalization. When more orbitals are taken into account or for calculating general two-particle Green’s functions with three independent frequencies, continuous-time quantum Monte Carlo (CT-QMC) approaches\textsuperscript{6,7} are the method of choice.

The core of the w2dynamics package is a CT-QMC calculation of $n$-particle Green’s functions for a generalized SIAM using the hybridization expansion (CT-HYB);\textsuperscript{8} closely related codes are ALPS,\textsuperscript{9,10} TRIQS,\textsuperscript{11} and EDMFTF.\textsuperscript{12} The CT-HYB approach expands the partition function in terms of the bath hybridization and stochastically samples the resulting determinants of the diagrammatic series. We employ the matrix-vector technique for the local time evolution.\textsuperscript{7} Furthermore worm sampling is used to compute most general two-particle Green’s functions\textsuperscript{13} and improved estimators are used for the self-energy\textsuperscript{14} which help reduce the CT-HYB’s signal-to-noise ratio which is particularly problematic at high frequencies.\textsuperscript{14}

The CT-HYB algorithm of w2dynamics might serve directly to study quantum dots connected to non-interacting leads or magnetic impurities in weakly interacting solids. Dynamical mean field theory (DMFT),\textsuperscript{15} on the other hand, maps Hubbard-like lattice Hamiltonians onto the self-consistent solution of a SIAM. Indeed a major application of w2dynamics is the solution of lattice Hamiltonians within DMFT. These might be model systems or, for materials calculations, Hamiltonians derived from \textit{ab initio} calculations such as density functional theory (DFT)\textsuperscript{16,17} or the \textit{GW} approximation.\textsuperscript{18}

The most widely approach of the latter kind is DFT+DMFT,\textsuperscript{19,20,21,22} others approaches include \textit{GW}+DMFT\textsuperscript{23,24} and more general embedding schemes.\textsuperscript{25,26} All these methods first attempt to identify the correlated subspace, map that space onto an effective model Hamiltonian by estimating the model parameters, correct for double counted contributions already included in the \textit{ab-initio} calculation, and finally find an (approximate) solution for this \textit{ab initio}-derived model Hamiltonian. The last step is provided by w2dynamics which includes an interface to wannier90\textsuperscript{27} generated Hamiltonians, obtained e.g. from Wien2k\textsuperscript{28} through the wien2wannier interface.\textsuperscript{29} Depending on the method employed, the w2dynamics results of the subspace might need to be embedded again into the full \textit{ab-initio} space, and one might (optionally) iterate the whole procedure until self-consistency.\textsuperscript{30,31,32}

While DMFT is restricted to site-local correlations, post-DMFT methods aim at including non-local correlations on top of DMFT. One route to this end are cluster extensions\textsuperscript{33} of DMFT which consider a cluster of sites within a DMFT-like bath. In principle, w2dynamics allows for such calculations by considering the whole cluster as the impurity, but with CT-HYB one is faced with a severe sign problem already at moderate cluster sizes. Other CT-QMC methods fare better in this case, but are restricted to single orbitals and/or density-density-like interactions.\textsuperscript{7}

Another route are diagrammatic extensions of DMFT.\textsuperscript{34,35,36,37,38,39,40,41} These require the calculation of the local two-particle vertex which depends on three frequencies and can be calculated by w2dynamics; simplified variants\textsuperscript{39} are based on three-leg (two-frequency) vertices while at an higher order in the expansion around DMFT (or for an error estimate) also three-particle vertices are required.\textsuperscript{42} One of the strong points of w2dynamics is the calculation of general multi-orbital two-particle Green’s functions, which are needed to obtain
the local vertices of post-DMFT approaches and for calculating DMFT susceptibilities. This is based on an intensive code and algorithmic development, including worm sampling,\textsuperscript{13} improved estimators,\textsuperscript{14} and vertex asymptotics;\textsuperscript{43} w2dynamics can also be employed to calculate selected three-particle Green’s functions.\textsuperscript{42} From the local vertex calculated by w2dynamics, the diagrammatic extensions of DMFT determine in turn non-local vertices and self-energies, using ladder or parquet diagrams.\textsuperscript{41}

The outline of the paper is as follows: A description of the code is provided in Sections \textsuperscript{2} and \textsuperscript{3}. Here, Section \textsuperscript{2} provides an overview of the Python scripts for doing self-consistent DMFT calculations of various types, which wrap around the CT-HYB code. Section \textsuperscript{3} in turn outlines the CT-HYB code for solving the SIAM. This includes the Monte Carlo steps of e.g. inserting and removing hybridization lines in Section \textsuperscript{3.1}, routines for estimating physical observables in Section \textsuperscript{3.2} and the calculation of the local and bath weight in Section \textsuperscript{3.3} and \textsuperscript{3.4} respectively. Section \textsuperscript{4} provides a brief description on how to install and run the code; and Section \textsuperscript{5} describes which parameters the user can (has to) set and the format of the hdf5 data output. These latter two, user-oriented Sections only provide a very first introduction, for further details we refer the reader to the online tutorial and wiki (cf. Section \textsuperscript{4.1}). Finally, Section \textsuperscript{6} provides a conclusion.
2. Dynamical mean field theory (DMFT) solver

Before turning to the w2dynamics solution of a SIAM, let us discuss the Python scripts that allow for an outer DMFT loop. This DMFT treatment allows us to deal with Hubbard-like lattice model, which in full generality can be written as:

$$\hat{H}_{\text{int}} = \sum_{R,R',I,I'} \sum_{\mu\nu} \hat{H}_{\mu,\mu'}^{(I,I')} (R, R') \hat{c}^{\dagger (I)}_{\mu} (R) \hat{c}^{(I')}_{\nu} (R')$$

$$+ \frac{1}{2} \sum_{R} \sum_{I} \sum_{\kappa\lambda\mu\nu} U_{\kappa\lambda\mu\nu}^{(I)} \hat{c}^{\dagger (I)}_{\kappa} (R) \hat{c}^{\dagger (I)}_{\lambda} (R) \hat{c}^{(I)}_{\nu} (R) \hat{c}^{(I)}_{\mu} (R).$$

Here, $\hat{c}^{(I)}_{\mu} (R)$ annihilates a fermion, $R$ denotes the coordinates of a unit cell or supercell, $I$ denotes the atom index within a supercell, and $\mu$ runs over spin-orbitals. $\hat{H}$ parameterizes the quadratic or non-interacting term, while $U$ parameterizes the interaction, which is assumed to be local for each atom. With bold typeface we indicate full matrices in the basis of all “correlated” and “ligand” spin-orbitals (included in the low-energy subspace) of all atoms of the unit cell; while non-bold-typeface tensors are restricted to the “correlated” space only as e.g. the Coulomb interaction. The small hat-symbol indicates that the quantity is a vector or a matrix, even if restricted to one of the atoms of the unit cell. The corresponding basis is defined by all spin-orbitals of the low-energy subspace associated to that atom.

The DMFT code is implemented in Python, since the challenges there are mostly conceptual, and Python allows for a more compact and clearer implementation. Most of the numerical problems are standard matrix operations as well as fast Fourier transforms, which can be deferred to the numpy package at essentially no loss of computing speed. For the CT-QMC solver (see Section 3), this is not a viable strategy. Instead, it has been implemented in Fortran 90, and the interface is mediated by the f2py interface generator included with numpy.

The different parts of the DMFT loop were carefully modularized in order to allow for their effective unit testing and re-use in different codes. A high-level UML class diagram is shown in Figure 1 which is centered around the “driver class” DMFTStep. In the following, we will explain the working of the code by going through the different modules in the code.

Lattice. This module defines an abstract class Lattice for the computation of the local Green’s function $\hat{G}_{\text{loc}}(i\nu)$. With bold typeface we indicate again all quantities within the full basis of all “correlated” and “ligand” spin-orbitals (included in the low-energy subspace) of all atoms of the unit cell. The local Green’s function is calculated from the $k$-integrated Dyson equation for the lattice model

$$\hat{G}_{\text{loc}}(i\nu) = \frac{1}{N_k} \sum_{k} \left[ (i\nu + \mu) \hat{1} - \hat{H}(k) - \hat{\Sigma}(i\nu) - \hat{\Sigma}_{\text{DC}} \right]^{-1}.$$  \hspace{1cm} (2)

This is the definition used by setting DOS=ReadIn, the definition Eq. (2) is directly realized using $\hat{H}(k)$ (read in from HkFile) on the given grid of $k$-points. With DOS=Bethe the code replaces, for the special case of a Bethe lattice, the $k$-summation by an integral over a semicircular density of states. DOS=nano gives the possibility of adding frequency-dependent functions describing the (physical) hybridization to non-interacting external leads, see Refs. 44,45.
Figure 2: Example of the atom, spin and orbital structure of the single-particle Hamiltonian $\hat{H}(k)$ (at a fixed $k$-point), input for DOS=ReadIn. The unit cell of this example contains three atoms, the first one with $e_g$-orbitals only, the second with the full $d$-shell and the third with a $x^2 - y^2$-orbital and two ligands (called here “p”). Each element of this Hamiltonian matrix has to have a real and an imaginary part. The only syntax requirement for the DMFT loop to work correctly is that for each atom, the “correlated” orbitals (in this case the $d$ ones) have to come before the “uncorrelated” ones.

The code supports calculations at a fixed total filling $N_{\text{target}}$ by adjusting the chemical potential to $N(\mu) = N_{\text{target}}$. For a $k$-discretized Hamiltonian this root finding for $\mu$ involves a series of local Green’s function computation at different $\mu$. This may easily become the bottleneck of the code for large systems since it scales as $O(N_{fl}^3 N_k N_\omega N_{it})$, where $N_{fl}$ is the number of spin-orbitals, $N_k$ is the number of $k$-points, $N_\omega$ is the number of frequencies, and $N_{it}$ is the number of iterations in the root finder. One can however pre-compute the eigenvalues of $(\hat{H} - \hat{\Sigma})$, store them as $\eta_i(k, \nu)$, and rewrite the density as:

$$N(\mu) = \frac{1}{\beta} \sum_{\nu} \text{tr} \hat{G}_{\text{loc}}(i\nu) = \frac{1}{\beta N_k} \sum_{k,\nu}^{N_{it}} \sum_{i=1}^{N_{fl}} e^{-i\nu\eta^-} \text{tr} \hat{G}_{\text{loc}}(i\nu).$$

This is a CPU–memory tradeoff as it reduces the scaling to $O(N_{fl}^3 N_k N_\omega) + O(N_{it} N_{fl} N_k N_\omega)$ while requiring $O(N_{fl} N_k N_\omega)$ of memory. If not enough memory is available, the code falls back to the direct strategy.

The lattice code itself is (trivially) parallelized over frequency since instead of $N(\mu)$ the trace over $\hat{G}_{\text{loc}}(i\nu)$ and the corresponding model is computed, which can then be summed at a higher level.

**Atom.** There are several reasons why realistic calculations of materials often require several “correlated” atoms, $I = 1, \ldots, N_{\text{at}}$, in the unit cell: among others magnetic supercells, heterostructures and surfaces. To some extent, the choice of which orbitals belong to the same atom is arbitrary and it lies in the responsibility of the user that the grouping into “atoms” is consistent with the (local) interaction parameters used between the orbitals.

In single-site DMFT, there are only intra-atomic self-energies and no self-energies between different atoms. $\hat{\Sigma}(i\nu)$ is therefore an atom-block-diagonal matrix in the basis sketched in Fig. 2 whereas $\hat{H}(k)$ contains instead hoppings between atoms as well as intra-atomic local and non-local elements. One can go from the full basis of all $N_{fl}$ “flavors”
within the supercell (i.e., atom, spin and orbital flavor; full matrix as sketched in Fig. 2) to
the block of a given atom $I$ with $N_{fl}^{I}$ flavors (spin and orbital; block Atom $I$ in Fig. 2):

\[
\hat{G}^{(I)}(i\nu) = D_I \hat{G}_{\text{loc}}(i\nu) D_I^{tr}, \\
\hat{\Sigma}(i\nu) = \sum_{I=1}^{N_{\text{at}}} D_I^{tr} \hat{\Sigma}^{(I)}(i\nu) D_I,
\]

where $D_I$ is the $N_{fl}^{(I)} \times N_{fl}$ matrix that projects (“downfolds”) to the impurity problem of the $I$-th atom with $N_{fl}^{(I)}$ local degrees of freedom; $\hat{G}^{(I)}$ and $\hat{\Sigma}^{(I)}$ are the corresponding local Green’s function and self-energy matrices, respectively. In our case, $D_I$ just projects out some rows and columns of the lattice problem (Fig. 2). The transposed $N_{fl} \times N_{fl}^{(I)}$ matrix $D_I^{tr}$ allows for an extension (“upfolding”) of atom $I$-based quantities to the full supercell of all atoms through Eq. (4b), and satisfies $D_I D_I^{tr} = \delta_{IJ} 1^{(I)}$. The up- and down-folding procedure is handled by the Atom class.

What we call here “$p$”- or ligand-orbitals are degrees of freedom that enter the low-energy problem and can hence exchange electrons with the “correlated” subspace of the “$d$”-orbitals. These “$p$”-orbitals are treated as non-interacting, have a vanishing self-energy and do not need to be included in the CT-QMC for the SIAM. The code can however also take care of an explicit Hartree contribution by setting $U_{pp}$ and $U_{pd}$ kind of interactions between the “$p$”-orbitals and between “$p$”- and “$d$”-orbitals respectively. Please note that also the double counting becomes important if both, “$p$”- and “$d$”-orbitals are included; it may also include a contribution from an Hartree-like frequency-independent self-energy associated to these “spectator” degrees of freedom.

The code can take local equivalence of atoms into account to minimize the number of impurity problems that have to be solved (class InequivalentAtom). If the parameter EPSEQ (see Sec. 5) is set, the code will attempt to detect whether two atoms are equivalent by comparing their $G_{0}^{-1}$ matrices and the interaction $U$. The user can either tune EPSEQ or set its own equivalence pattern. Magnetic biases given in the initial configuration (se-shift) as well as different interaction parameters also influence the equivalence pattern.

Both considering the “$p$”-orbitals as non-interacting as well as ignoring correlation between atoms inside a super-cell allows one to work around the exponential scaling of the impurity solver with the number of impurity orbitals. Let us note here, that as a matter of course the user can also include all atoms of the supercell into one w2dynamics “atom”. In this case also correlations and self-energy elements between the physical atoms are included, at the expense of the increasing computational burden.

Local interaction. The code supports different parameterization of the local interaction Hamiltonian, summarized in Table 1.

These can be selected by choosing the parameter with the name Hamiltonian (capable of being misunderstood), in the [Atoms] section. The simplest one is the “density-density” scheme (Density), where only two-body interactions that can be written in terms of orbital occupations appear. The couplings of this kind of interaction are set via the parameters $U_{dd}$, representing the local Hubbard repulsion, the Hund coupling $J_{dd}$ and $V_{dd}$, which need not fulfill specific relation with the other two parameters. Note that the inclusion of $J_{dd}$ in the density-density scheme breaks SU(2) symmetry, since spin flip and pair hopping terms cannot be cast in this form. These parameters are used uniformly for all orbitals of the given
ReadUmatrix reads a tensor with four orbital and four spin indices. Reading in the crystal field eigenfunctions or directly from constraint random phase approximation (cRPA).

	| Hamiltonian      | Parameters | \( H_{\text{int}} = \)                                                                 |
|------------------|------------|----------------------------------------------------------------------------------------|
| Density          | Udd, Jdd, Vdd | \( H_{\text{dd}} = \sum_{i} U_{ni\sigma} n_{j\sigma} + \sum_{i<j} (V - J_{\sigma\sigma'} n_{i\sigma} n_{j\sigma'}) \) N, S_z, n_{i\sigma} |
| Kanamori         | Udd, Jdd, Vdd | \( H_{\text{dd}} - J \sum_{i<j} (\hat{c}_{i\uparrow}^\dagger \hat{c}_{j\uparrow} + \hat{c}_{i\downarrow}^\dagger \hat{c}_{j\downarrow}) \) N, S_z, PS |
| Coulomb          | F0, F2, F4  | \( \sum_{n} F_{i\kappa} \) \( N, S_z, L_{\kappa} \)                                      |
| ReadUmatrix      | Umatrix     | \( \frac{1}{2} \sum_{ijkl} U_{ijkl} \sum_{\sigma\sigma'} c_{i\sigma}^\dagger \hat{c}_{j\sigma'} \hat{c}_{l\sigma'} \hat{c}_{k\sigma} \) \( N, S_z \) |

Table 1: Available parametrizations of the local interaction. \( \hat{c}_{\sigma} \) annihilates a fermion on the corresponding impurity, \( n_{i\sigma} = \hat{c}_{i\sigma}^\dagger \hat{c}_{i\sigma} \) is the corresponding density operator, \( i, j, k, l \) are impurity orbitals and \( \sigma, \sigma' \) denote spins. \( N = \sum \langle n_{i\uparrow} + n_{i\downarrow} \rangle \) is the total occupation, \( S_z = \sum \langle n_{i\uparrow} - n_{i\downarrow} \rangle \) the total spin in \( z \) direction and PS denotes the pattern of singly-occupied orbitals (see Ref. 53 for a definition).

An orbital-dependent density-density type interaction can be set by using a special the ReadNormalUmatrix scheme.

\textbf{Hamiltonian=Kanamori} adds the pair-hopping and spinflip terms to the density-density interaction, thus restoring the SU(2) symmetry.\(^{54}\) This interaction scheme conserves the so-called “PS”-quantum number,\(^{55}\) which allows for a tighter block structure of the local Hamiltonian and thus efficient sampling.

With \textbf{Hamiltonian=Coulomb} the interaction matrix for a complete \( d \)-shell is generated from the Slater parameters \( F_0, F_2 \) and \( F_4 \) in spherical harmonics, and then transformed to the crystal field basis.

The other possibility is to use \textbf{ReadNormalUmatrix} in which a tensor of four orbital indices is expected as input (\texttt{umatrix="filename"}). This tensor represents a \( U_{ijkl} \) full Coulomb tensor, e.g. coming either from spherical Coulomb tensors written in the basis of the cubic crystal field eigenfunctions or directly from constraint random phase approximation (cRPA). \textbf{ReadUmatrix} reads a tensor with four orbital and four spin indices. Reading in the \( U_{ijkl} \) tensor, the user has still the possibility of neglecting elements with a specific structure, for instance removing all entries that are not of the Kanamori type. This may be useful, for instance, in Kanamori calculations of the full \( d \)-shell, for which one however wants to keep the difference between intra-\( t_{2g} \) and intra-\( e_g \) Hund’s couplings. Let us note that if this is used in combination with “\( d-p \)” calculations, the user is advised that the double-counting values have to be set by hand rather than relying on the “automatic” calculation by w2dynamics.

For general interactions, the code automatically finds the structure of the local part of the impurity Hamiltonian with the minimal block size (by adding \texttt{All} to the \texttt{QuantumNumber} list).\(^{56}\)

In the case of density-density type of local interactions, the code supports the addition of a retarded interaction term \( W^{(I)} \) by setting the \texttt{Screening} parameter. This modifies the effective impurity action as follows:\(^{57}\)

\[
S^{(I)}[c, c^*] \to S^{(I)}[c, c^*] + \frac{1}{2} \sum_{\mu \nu} \left( \int \text{d}^2 \tau \ c^*_\mu(\tau) c^*_\mu(\tau) W^{(I)}_{\mu \nu}(\tau - \tau') c^*_\nu(\tau') c^*_\nu(\tau') \right). \tag{5}
\]

\textbf{ImpurityProblem}. At each step of the DMFT loop, \( N_{\text{at}} \) impurity problems are generated from the local Green’s function of Eq. (2). The code calculates, for each atom \( I \), the following...
Weiss field matrix \cite{58,59,22}:

\[
\left( \hat{G}^{(I)}(i\nu) \right)^{-1} = \left( D_I \hat{G}(i\nu) D_I^{-1} \right)^{-1} + \hat{\Sigma}^{(I)}(i\nu),
\]

where \( \hat{G} \) again denotes the full local Green’s function of dimension \( N_{fl} \times N_{fl} \), while \( \hat{\Sigma}^{(I)} \) and \( \hat{G}^{(I)} \) denote the self-energy and Weiss field, respectively, of the \( I \)’th atom and are of dimension \( N_{fl}^{(I)} \times N_{fl}^{(I)} \). These Weiss fields, or the hybridization functions \( \Delta \) related through Eq. (9), define \( N_{at} \) auxiliary single-site quantum many-body impurity problems. Each inequivalent impurity problem is then solved by \texttt{ImpuritySolver.solve()}, yielding the two-point Green’s function of the \( I \)-th atom \( \hat{G}_{\text{imp}}^{(I)}(i\nu) \). The corresponding self-energy is obtained via the Dyson equation

\[
\hat{\Sigma}^{(I)}(i\nu) = \left( \hat{G}^{(I)}(i\nu) \right)^{-1} - \left( \hat{G}_{\text{imp}}^{(I)}(i\nu) \right)^{-1}.
\]

Once the self-energy matrices for all atoms are calculated via Eq. (7), the full matrix \( \hat{\Sigma}(i\nu) \) is constructed block-wise and inserted back into Eq. (2). This way \texttt{ImpurityResult} generates a new local Green’s function for the whole system. The self-consistency loop then goes on by calculating Eq. (6) for each site again etc. The user is responsible to decide when convergence is reached. To help the stabilization of the DMFT self-consistency loop we mix the previous and the current self-energies, according to the parameter \texttt{mixing} (a value of 0 means that the solution has no contribution from the previous iteration, whereas 1 means that the self-energy is entirely given by that at the previous iteration).

3. CT-HYB impurity solver

The hybridization expansion continuous-time quantum Monte Carlo (CT-HYB) solver provides an unbiased solution to Anderson impurity models arising e.g. from the self-consistent solution of the DMFT equations. The impurity Hamiltonian, in its full generality, can be written as:

\[
H = H_{\text{loc}}[\hat{c},\hat{c}^\dagger] + H_{\text{hyb}}[\hat{c},\hat{c}^\dagger,\hat{f},\hat{f}^\dagger] + H_{\text{bath}}[\hat{f},\hat{f}^\dagger] \\
= \sum_{\kappa\lambda} E_{\kappa\lambda\lambda} \hat{c}_\kappa^\dagger \hat{c}_\lambda + \frac{1}{2} \sum_{\kappa\lambda\mu} U_{\kappa\lambda\mu\nu} \hat{c}_\kappa^\dagger \hat{c}_\lambda^\dagger \hat{c}_\mu \hat{c}_\nu + \sum_{\kappa p} (V_{p\kappa} \hat{f}_p^\dagger \hat{c}_\kappa + \text{h.c.}) + \sum_p \tilde{E}_p \hat{f}_p^\dagger \hat{f}_p,
\]

where \( \hat{c}_\lambda \) annihilates a fermion of spin-orbital \( \lambda \) on the impurity and \( \hat{f}_p \) annihilates a fermion on the bath, where the quantum number \( p \) can be continuous. For the \( I \)-th impurity problem, the interaction tensor is \( U = U^{(I)} \), and the quadratic part is given by

\[
\left( \hat{G}^{(I)} \right)^{-1}_{\lambda\mu}(i\nu) = (i\nu + \mu) \delta_{\lambda\mu} - E_{\lambda\mu} - \hat{\Delta}^{(I)}_{\lambda\mu}(i\nu)
\]

with the hybridisation function

\[
\hat{\Delta}^{(I)}_{\lambda\mu}(i\nu) = \sum_p \frac{V_{p\lambda} V_{p\mu}^*}{i\nu - \tilde{E}_p}.
\]
CT-HYB expands the partition function $Z$ of that SIAM, defined by $H$ and the inverse temperature $\beta$, in terms of the hybridisation $H_{hyb}$ (for a derivation, see Ref. 7):

$$
Z = \sum_{k=0}^{\infty} \int_0^{\beta} \prod_{i=1}^k d\tau_i \ d\tau'_i \sum_{\lambda_i'} \text{tr} \left[ T_\tau e^{-\beta H_{loc}} \prod_{i=1}^k \hat{c}_{\lambda_i}^\dagger(\tau_i)\hat{c}_{\lambda_i'}(\tau'_i) \right] \det \left[ \Delta_{\lambda_i \lambda_j}(\tau_i - \tau'_j) \right]_{ij} .
$$

(11)

Here $T_\tau$ is the time-ordering operator, $H_{loc}$ the local Hamiltonian of the impurity, cf. Eq. (8) and $\Delta$ is the hybridisation function, cf. Eq. (10). CT-HYB thus corresponds to the sampling over all diagrams with vertices at $\lambda_i, \lambda'_i, \tau_i, \tau'_i$, and the weight of each diagram is given by the product of a local weight, $w_{loc}$, and a bath weight, $w_{bath}$. Here, the local weight or local trace is given by

$$
w_{loc} = \text{Tr} \left[ T_\tau e^{-\beta H_{loc}} \prod_{i=1}^k d_{\lambda_i}(\tau_i) d_{\lambda_i'}(\tau'_i) \right] ,
$$

(12)

which is represented by LocalTrace in the UML Figure 3 and will be discussed in detail in Section 3.3. The bath part of the weight $w_{bath} = \det \Delta$ (BathTrace in Figure 3) is the determinant of noninteracting hybridization functions, whose calculation will be detailed in Section 3.4. The Monte Carlo importance sampling of different flavors $\lambda_i$, imaginary time positions $\tau_i$ and expansion orders $k$ in the sum of Eq. (11) is realized through Steps as outlined in Section 3.1. The Monte Carlo measurement of observables, on the other hand, is performed by Estimator as discussed in Section 3.2.

The CT-QMC solver is written in Fortran 90 in order to account for numerical efficiency when sampling the Monte Carlo configuration space. Since Monte Carlo algorithms are trivially parallelizable, we offset the communication and averaging work to the Python infrastructure. Consequently, the Fortran modules are entirely unaware of any parallelization schemes.
| move type            | \( R_{\text{prop}} \)                                                                 | move type            |
|----------------------|----------------------------------------------------------------------------------------|----------------------|
| pair insertion       | \( \frac{N\beta^2}{(k+1)^2} \)                                                       | pair removal         |
| quadruplet insertion | \( \frac{N^4\beta^4}{(k+2)^4} \)                                                     | quadruplet removal   |
| pair flavor change   | \( \frac{k^2N^2}{k^2N^2} \)                                                           | pair flavor change   |
| operator shift       | \( \frac{k^2\beta}{k^2\bar{\beta}} \)                                                 | operator shift       |
| flavour permutation  | \( \frac{N!}{N!} \)                                                                   | flavour permutation  |
| worm insertion       | \( \frac{\eta N^2\beta^2}{\bar{\eta} N^2} \)                                         | worm removal         |
| worm replacement     | \( \frac{2k}{2k} \)                                                                  | worm replacement     |

Table 2: Available updates of a configuration in CT-HYB. The center column is a diagrammatic representation of the update, where the horizontal line represents the imaginary time axis \( \tau \in [0, \beta] \), filled and empty diamonds represent local creation and annihilation operators, respectively. Vertical lines attached to operators indicate the presence of hybridization lines, i.e., operators coming from the hybridization expansion, while the absence of such lines signifies purely local, i.e. worm, operators. \( R_{\text{prop}} \) denotes a prefactor for the relative probability of the two configurations, which needs to be multiplied to the ratio of the local and bath weights discussed in Sections 3.3 and 3.4, respectively. Here \( N \) is the number of impurity spin-orbitals, \( k \) the expansion order, and \( \eta \) the balancing parameter between worm and partition function space.

The impurity solver is structured into several layers arranged in order of increasing complexity. On the lowest level this includes matrix operations and the random number generator. The intermediate level includes routines for defining many-body operators and states. These are used in the definition of the local problem and the bath problem. On the highest level, the simulation block governs the Metropolis Hastings Monte Carlo procedure. Monte Carlo steps and estimators are defined for the partition function space and the worm space.

3.1. Steps

The expansion of the thermal expectation value of the partition function (or equivalently, any Green’s function like object) results in an infinite series of Feynman diagrams which is sampled through the Metropolis Hastings Monte Carlo algorithm. In the case of CT-HYB this is a series in terms of hybridization inclusions, see Table 2. Thus, the Monte Carlo sampling procedure takes place in the space of all possible Feynman diagrams. In order to fulfill ergodicity and (detailed) balance, it is necessary to define Monte Carlo steps, which
increase and decrease the expansion order of the infinite series. We usually relate to these steps as 'add' and 'remove'.

Further Monte Carlo steps allow us to change the observable we sample (worm sampling) or decrease auto-correlation lengths (global moves in partition function space and replacement moves in worm space).

**Partition Function Sampling.** When expanding the partition function in the hybridization, the set of possible diagrams depends on the type of local interaction considered. The diagrammatic series built from general local interactions includes Feynman diagrams, which are not present in the diagrammatic series built from simplified local density-density interactions only. This is because the imaginary time propagation between creation and annihilation operators in Table 2 may then include e.g. a spin flip in two different orbitals. Although in both cases the 'add' and 'remove' steps alter the local weight and the bath weight of the configuration, as discussed in Sections 3.3 and 3.4, respectively. In the segment representation these steps can be reformulated in a more compact form, resulting in a higher acceptance rate than the one of the matrix-vector representation. Consequently, the configuration space is sampled faster. Both algorithms profit from fast update formulas in the bath determinant. The percentage for attempted insertion and removal steps is implicitly determined by setting the percentages for attempting all remaining steps.

While 'add' and 'remove' steps alter the diagrammatic series by changing a small subset of operators only, one can further formulate global moves, which act on all creation and annihilation operators of the current configuration. These are computationally more expensive, as they require a complete reevaluation of the configuration weight. In the paramagnetic case, the otherwise explicit symmetrization over spins may be imposed onto the system by proposing to flip the spins of all the operators at the same time. This is done for a fixed percentage of the global moves. If certain symmetries of the systems are known beforehand, operator permutations may be specified in the parameters file with **SymMove01** to **SymMove99** and an additional parameter **NSymMove** is specifying the number of symmetry moves. This is done for the remaining fifty percent of global moves. Lastly, random permutations of the operator flavours in the trace are performed for the remaining global moves. The total percentage of attempted global moves is specified with the parameter **PercentageGlobalMoves**.

**Worm Sampling.** Instead of sampling the diagrammatic series of the partition function and extracting an observable by altering individual configurations, one may choose to sample an observable directly. Switching from partition function space (the diagrammatic series given by the denominator of the thermal expectation value, i.e. importance sampling) to worm space (the diagrammatic series given by the numerator of the thermal expectation value) requires a new set of moves. Primarily, one is interested in extracting Green’s function like objects in this fashion, which is why configuration weights of worm spaces only differ from configuration weights of the partition function space by a set of additional local operators (in terms of diagrams these are the external legs). The moves switching between these two spaces are also of the type 'add' or 'remove', but here they only alter the local weight, leaving the bath weight unchanged. The corresponding percentage of attempted inserts and removes is specified with the parameter **PercentageWormInsert**. Within worm space, the sampling with operators connected to the bath is required in order to fulfill ergodicity.
Again, the percentage of attempted inserts and removes of such operator pairs is implicitly
determined by all remaining steps. While the global moves have not been implemented in
worm space, additional replacement steps exist. These attempt to change a specific worm
configuration by reattaching hybridization lines from a given operator to the worm operator
of the same flavor. The percentage of attempted replacements is specified by the parameter
PercentageWormReplace.

3.2. Estimators

Once the Monte Carlo sampling of the Feynman diagrammatic series expansion is estab-
lished, the remaining task is to extract physical observables. This procedure differs when
sampling the partition function series and when sampling the observable directly using worm
sampling, cf. Ref. 13.

Partition Function Sampling. The major quantities of interest are the one-particle (imagi-
nary time, Matsubara and Legendre basis) and the two-particle Green’s function (Matsubara
basis). From the respective Green’s functions, the one-particle and two-particle density ma-
trices can be obtained as the all-equal-time components. The histogram denotes the prob-
ability distribution of the expansion order \( k \), i.e., the number of pairs in Figure 1 (which
in the hybridization expansion depends on the kinetic energy). In order to measure an
\( n \)-particle impurity Green’s function in Partition Function Sampling mode, all hybridiza-
tion lines connected to \( n \) operators are removed, in order to create \( n \) purely local operators
that are disconnected from the bath (also coined “hybridization sampling”). In Table 2, this
corresponds to taking away the vertical line of \( n \) filled creation and \( n \) open annihilation
operators. Bosonic observables like the local DFMT charge susceptibility
\( \langle n_{i,\sigma}(\tau)n_{j,\sigma'}(0) \rangle \) or
spin susceptibility \( \chi_{\text{loc}}(\tau) \) are measured by insertion of density operators. A detailed list of
all relevant parameters and the name of the output quantities is given in Table 3.

Worm Sampling. The worm algorithm in continuous-time Quantum Monte Carlo algorithms,
such as CT-HYB, was introduced in order to allow for more flexibility in terms of the choice
of estimators. While partition function sampling restricts the observables to the diagrams
present in the infinite series expansion of the partition function, this is not true for worm
sampling. Instead, diagrams may be present in the expansion of the observable itself, which
are otherwise absent. This is especially true for the two-particle Green’s function, when
considering a diagonal hybridization function with non-density-density local interactions.
Further Green’s functions with a subset of the operators occurring at equal times can be
easily defined for general local interactions. These are important when extracting the high
frequency asymptotics of the fully time-dependent Green’s function. A detailed list of all
relevant parameters and the name of the output quantities is given in Table 3.2.

3.3. Local trace

The computation of the local weight \( 12 \) relates to the solution and, with each Monte
Carlo move, efficient update of an exact diagonalization problem with a Fock space size of
\( 2^{N_a} \). Apart from possible conditioning issues of the bath determinant, it is thus easily
the computational bottleneck for a CT-HYB calculation, and several strategies have been
developed to tackle the problem: matrix-matrix and matrix-vector codes implement the
| output | parameter(s) | estimator |
|--------|-------------|-----------|
| sign   | –           | $s = \langle \text{sgn } w \rangle_{\|w\|}$ |

Table 3: Measurable quantities in partition function and worm sampling
time-evolution of many-body states in the thermal expectation value.\cite{7} They are defined for any type of local interaction. The simpler segment representation applicable to density-density interactions is thought to be superior due to a favorable scaling in the number of orbitals and enhanced Monte Carlo acceptance rates. For an introduction into CT-HYB in its aforementioned variants see Refs. 7. The w2dynamics code features the matrix-vector implementation, combined with a newly developed superstate sampling method.\cite{w2dynamics}

In the case of density-density interaction, the time-evolution $e^{-H_{\text{loc}} \tau}$ gives only a prefactor to the many-body state, since there are only density operators in $H_{\text{loc}}$, which is diagonal in the occupation number basis. When, on the other hand, non-density-density interactions like Kanamori or the full-Hubbard terms are present in $H_{\text{loc}}$, the time-evolution mixes many-body states. For example, a Kanamori time-evolution applied to a state $| \uparrow, \downarrow >$ yields a state $\alpha | \uparrow, \downarrow > + \beta | \downarrow, \uparrow >$. In w2dynamics, for Kanamori and general interactions the time-evolution is implemented in the eigenbasis of the local Hamiltonian.

Each type of interaction has its conserved quantities (see Table \ref{1}). When hopping between different orbitals on the impurity is present, e.g. processes like $| \uparrow, 0 > \rightarrow | 0, \uparrow >$, the PS quantum number must be removed from the set of conserved quantities. In order to allow for hopping terms like $| \uparrow, 0 > \rightarrow | 0, \downarrow >$ where also the spin is not conserved, $S_z$ must be removed as a quantum number. Hopping terms are necessary to treat short range, non-local correlations within cluster-DMFT or magnetic fields with an $x$-component, complex hopping amplitudes in order to describe spin-orbit coupling or magnetic fields with an $y$-component. The real ones are switched on by $\text{offdiag}=1$, the complex ones will soon be available and can be switched on by $\text{complex}=1$.

Details on the way the local trace is calculated will be given in a separate publication.\cite{w2dynamics}

### 3.4. Bath trace

Using an ab-initio Hamiltonian $H(k)$, one usually gets offdiagonal hybridization functions $\Delta(\tau)$ as well as hopping terms $\mu^\text{imp}_{\alpha,\beta} c_\alpha^\dagger c_\beta$, which can be allowed by setting the parameter $\text{offdiag}=1$. By rotating the single particle basis these offdiagonal terms can be minimized but never removed for general offdiagonal hybridizations.

Density-density interactions and offdiagonal hybridization functions can be combined straightforwardly. For Kanamori and full-Hubbard interaction combined with offdiagonal hybridization functions complications arise, since interactions such as the spin-flip configuration $(c_2^\dagger c_1^\dagger c_2 c_1)$ or the pair-hopping configuration $(c_2^\dagger c_2^\dagger c_1 c_1)$ are contained in the configuration space. Their contribution is zero when the hybridization function is diagonal in the flavors. They cannot be generated by insertions and removals of pairs of operators, but by insertions or removals of 4 operators.\cite{complex_moves} Alternatively the spin-flip and pair-hopping configurations could be generated via so called flavorchange-moves, which change the flavour-indices of two operators, e.g. $c_1^\dagger c_1^\dagger c_1 c_1 \rightarrow c_2^\dagger c_2^\dagger c_2 c_2$. Flavorchange-moves have acceptance rates orders of magnitudes larger than the 4-operator moves, nevertheless we observe more noise with flavorchange-moves compared to 4-operator-moves.

By default 4-operator-moves are used, and switched on with the parameter $\text{Percentage4OperatorMove}$.\cite{percentage}
4. Installation and community site

4.1. Where to find the project and the code

We have decided to put the source code of this tool developed hitherto in Wien and Würzburg (hence the \textit{w2} in \textit{w2dynamics}) under the GNU GPL license Version 3, an established open source license. This should be the first, but very important step, towards building a larger community\textsuperscript{63} around this code. The goal of this community should be to work together to obtain a DMFT code that is flexible to embed into other tools via its python interface and flexible with regard to the simulatable unit cells. Following recent trends in the community we have set up a github repository at \url{https://github.com/w2dynamics/w2dynamics} that serves as a central meeting point on where to find the code. The code is available to the public and people can interact with the developers via the issue tracking facilities and the wiki pages so that members of our community can collect information they consider useful for the project. There is a public mailing list \texttt{w2dynamics-users@list.tuwien.ac.at} that is also frequented by the developers; and a second developers mailing list \texttt{w2dynamics-devel@list.tuwien.ac.at}. We think that it is beneficial to users to become a part of our community so that they can benefit from the experience of experts in solid state physics and Monte Carlo techniques. To bring together people from various backgrounds we plan to organize workshops and community meetings that everybody is able to attend. Using an open platform like github we have the technical means to trace the contributions of everybody, to make sure that every contributor is listed on our project website, or, in the case of greater contributions, to authorship on a relevant contribution. Organizing workshops, hosting the servers and investing the time takes some effort but we are committed to invest that to grow an open community.

4.2. Installation

Since the \textit{w2dynamics} code base tries to leverage the power of Fortran and the flexibility of python, the installation is a little bit more involved. In particular, some dependencies have to be taken care of. We tried our best to make the installation as simple as possible on as many platforms as possible. As build system we use cmake and we install a lot of the required dependencies if they can not be found on the user’s system. At the time of writing we strictly require cmake $\geq$ 2.8.5, a FORTRAN90 compatible Fortran compiler, a C++ compiler that at least exposes the C++11 RNGs since we only provide a trivial fallback, the BLAS and LAPACK libraries, a python interpreter version 2.4 or bigger, the FFTW library, and an implementation of the MPI API. Without these libraries the installation step will fail. We will automatically install any of the following packages if it is missing: Those packages are: the NFFT library, numpy $\geq$ 1.2, libhdf5 $\geq$ 1.6 with Fortran bindings, mpi4py, h5py, scipy $\geq$ 0.6 with f2py, and python-configobj. Note that the compilation of NFFT and libhdf5 necessitates a C compiler and the associated libraries. Python dependencies that are marked as optional will be downloaded and locally installed using the pip installer.

Let us assume (i) cmake is installed, (ii) the source files are downloaded, and (iii) the present working directory is the \textit{w2dynamics} root folder. Then the following cmake commands should give working binaries for the CT-HYB code and the Maxent utility:

\begin{verbatim}
mkdir build
cd build
\end{verbatim}
We routinely test the compilation of our code on various Linux distributions such as Ubuntu, Debian, OpenSuse and CentOS. After compilation, we recommend the reader to do the tutorial. To circumvent the problem of rapidly aging documentation we refer the reader to our wiki page at [https://github.com/w2dynamics/w2dynamics/wiki/Tutorial](https://github.com/w2dynamics/w2dynamics/wiki/Tutorial). Currently the tutorial shows some of the features of w2dynamics and solves the problem of a two-orbital model on a simple cubic lattice with applied crystal and magnetic fields.

The repository also includes additional test and benchmarks, which serves as a testbed for code development. The benchmarks have a structured layout and usually follow the same pattern. The user has to

- change to the directory of the benchmark which also contains a short description of the problem,
- inspect `Parameters.in`, which contains the parameters in key/value format (see Table 4),
- execute `DMFT.py` in this working folder.
- This produces an HDF5 archive with all simulation data (see Table 5)
- which can be accessed by the hgrep commands or the ipython notebook.

5. Input/output

Parameters. The w2dynamics code is mainly controlled by specifying a set of input parameters. Due to the versatility of the code a large amount of such input parameters exist, while most have reasonable default values pre-defined in 'auxiliaries/confispec'. By supplying a configuration file, these default values can be overwritten with user-defined values. A sample config file is distributed together with the code.

The configuration file is structured into the three sections [General], [Atoms] and [QMC], while the [Atoms] section consists of numbered subsections ([[1]], [[2]], ....) for each individual atom defined in the unit cell. A detailed list of mandatory user-defined parameters is given in Table 4.

HDF5 output. Any quantity measured by the impurity solver or calculated during the self-consistency cycle is stored in hierarchical data format (HDF5). Nowadays, this format is the de facto standard and is employed by the major DMFT software packages. File operations for reading and writing data from and to HDF5 are realized through the Python library `h5py`.

The output file consists of several hidden groups (".config", ".environment", ".axes" and ".quantities"), which store the meta-data of each run. The ".config" group stores all simulation parameters (user-defined or default values). The ".environment" group stores the entire shell-environment and further scheduler-parameters on clusters. The ".axes" stores Matsubara and imaginary time axes, which are shared between different quantities. The link between these quantities and the corresponding axis is defined in ".quantities".

Table 5: hdf5-file structure

Apart from the hidden group, the output file consists of several iteration groups (‘start’, ’dmfnt-’, ’stat-’, ’finish’). While ’start’ stores information about the non-interacting problem all other iteration groups store quantities further grouped by the inequivalent atoms. A detailed list is given in Table 5.

**hgrep utility.** For quick access to the data stored in the HDF5 file, the hgrep command line utility is included with the code. hgrep can extract a subset of the data stored in one or more HDF5 files, and tabulate or plot the resulting data. As an example, the following command:

```
  hgrep -p test.hdf5 siw 1:3 plot file \Sigma(iv) iterations atom(I) orbital j spin \sigma iv only imaginary part
```

plots the imaginary part of the impurity self-energy stored in the first test.hdf5 for the first three iterations (FORTRAN-style ranges are supported), impurity problem I = 1, orbitals 1 and 4, spin up, in the frequency range $0 \leq iv \leq 20$. A man page is available, which lists more detailed syntax and provides further examples.

6. Conclusions

We have described here the main features of the hybridization-expansion continuous-time quantum Monte Carlo code package “w2dynamics”. Users can calculate local two- and four-point fermionic Green’s functions of multi-orbital impurity models. These can be either isolated impurities attached to leads or auxiliary impurities in DMFT or DFT+DMFT calculations of lattice Hamiltonians. The level of approximation is the DMFT; w2dynamics does not introduce further approximations to the numerically exact CT-QMC algorithm (as e.g. inner or outer truncations of the local trace).

The w2dynamics package is similar in spirit to TRIQS\textsuperscript{11,62,64} and ALPS,\textsuperscript{9} all of which have their particular strengths. In the case of w2dynamics these are:

1. The calculation of arbitrary one- and two-particle Green’s functions and local physical susceptibilities. This serves as an input for subsequent calculations of physical susceptibility and for diagrammatic extensions of DMFT\textsuperscript{41} that use the local vertex as
a building block. The package directly interfaces with post-DMFT packages such as AbinitioDGA and LadderDGA.  

2. Improved sampling techniques such as worm and superstate sampling. Worm sampling overcomes the limitations of the standard hybridization measurement in partition function sampling, and allows to directly estimate all components of the n-particle Green's function including equal-time dynamic susceptibilities, improved estimators for the self-energy, and asymptotics of the four-point vertex. Moreover, it extends the applicability of the CT-HYB algorithm to strongly insulating multi-orbital systems, where partition function sampling suffers from severe ergodicity problems.  

3. A large versatility of four-fermion interactions, ranging from the simplest density-density, to the rotationally-invariant Kanamori to the most general full Coulomb four-index tensor. Retardation effects (such as coming from electron-phonon interaction or cRPA screening) can be taken into account.  

4. A flexible way of interfacing to DFT calculations also for materials with large unit cells made of atoms that can be inequivalent regarding symmetry, number of correlated orbitals, number of ligands, values of the Coulomb interaction, spin orientation, and so on. The input of wannier90 generated Hamiltonians, after a transformation to k-space, is possible.  

5. Treating magnetic phases and off-diagonal hybridization functions which may stem e.g. from (real-valued) inter-orbital hoppings. Future releases will offer full support for complex inter-orbital and inter-spin elements in order to run calculations with spin-orbit coupling.  

Acknowledgments  
We are indebted to M. Ferrero for his help in the early stages of this project and to B. Hartl, J. Kaufmann, P. Chalupa, M. Schüler and D. Springer for contributions to the development of the w2dynamics package. We thank these as well as E. Gull, P. Werner, A. Toschi, J. Tomczak, J. Kuneš, D. Di Sante, M. Aichhorn, A. Hariki for helpful discussions. Financial support is acknowledged from the Austrian Science Fund (FWF) SFB ViCoM F41 (MW), the Deutsche Forschungsgemeinschaft (DFG) research unit through SFB1170 (AH,AK,FG,GS) and research unit FOR 1346 (AH,KH,GS), the Vienna Scientific Cluster (VSC) Research Center funded by the Austrian Federal Ministry of Science (PG), and the European Research Council under the European Union’s Seventh Framework Program (FP/2007-2013) through ERC grant n. 306447 (KH). AH,AK,FG and GS gratefully acknowledge the Gauss Centre for Supercomputing e.V. for funding this project by providing computing time on the GCS Supercomputer SuperMUC at Leibniz Supercomputing Centre (LRZ).
