INTRODUCTION

According to statistics recently announced by the Division of Cancer Registration and Surveillance of the National Cancer Center, the incidence of colorectal cancer is increasing in Korea. \(^1\) Fifteen to twenty percent of colorectal cancer patients have symptoms of intestinal obstruction symptom at the time of diagnosis. \(^2\) Intestinal obstruction occurs in 7 to 30% of patients with tumors located in the distal colon of splenic flexure. \(^3\) Emergency surgical resection is often necessary in patients with obstructive colorectal cancer which has an increased risk of anastomosis leakage due to dilatation...
of proximal colon, ileus, and edema. Emergency surgery also requires stoma formation, and is more likely to need a two-step operation.\(^4,5\)

Since the use of metal stenting was first reported by Dohmoto et al. in 1991, stent placement has facilitated the transition from emergency surgery to elective surgery by decompressing the malignant colorectal obstruction.\(^6,9\) Stenting as a bridge to surgery makes it possible to avoid stoma formation, allowing the possibility of primary anastomosis. However, stent-related complications are possible including stent dislodgement, bleeding, and perforation. There are also concerns about local cancer recurrence attributable to stenting because of subclinical perforation.\(^10-13\)

Stent placement is set as a standard procedure for malignant obstruction in many tertiary referral hospitals including our institution. This study aimed to investigate the safety, efficacy, and oncologic results for stent placement as a bridge to surgery for left colon and rectal cancer obstruction.

**MATERIALS AND METHODS**

The hospital records of all patients who had surgery for malignant colorectal cancer from September, 2006 to October, 2014, at Korea University Anam Hospital were retrospectively reviewed. A total of 2,552 patients had surgery for malignant colorectal cancer. Of these patients, those who had been treated for left colon cancer and rectal cancer with total obstruction were enrolled. The left colon was defined as between the distal transverse colon and rectum. Colorectal cancer total obstruction was defined as intestinal obstruction confirmed through colonoscopy and computed tomography (CT) imaging.

The decision for stent placement was collaboratively made by surgeons and gastroenterologists at our hospital. Emergency surgery was performed in cases of bleeding, perforation with panperitonitis, severe pain suggestive of intestinal ischemia, mid to low rectal tumor location, and for cases of a large fixed mass with a high risk of impending perforation with stenting.

Stents were inserted through an endoscope. Self-expandable metallic uncovered stents (M.I. Tech, Gyeonggi-do, Korea) were used with sizes ranging from 20~22 mm in diameter and 80~140 mm in length. All stents were placed under endoscopic and fluoroscopic guidance. Technical stent success was defined as successful deployment with fluoroscopic confirmation. The duration from stent placement to elective surgery was established as 7~10 days in our institution.

All data were prospectively collected in a database and

| Table 1. Patient demographics and tumor characteristics |
|---------------------------------------------------------|
| **SP (n = 53)** | **EM (n = 14)** | **p** |
| Age, mean ± SD | 66.3 ± 11.5 | 65.4 ± 14.3 | 0.819 |
| Sex | | | 0.169 |
| Male | 33 (62.3%) | 6 (42.9%) | |
| Female | 20 (37.7%) | 77 (34.1%) | |
| BMI (kg/m²), mean ± SD | 22.4 ± 3.0 | 22.3 ± 2.3 | 0.819 |
| Preoperative CEA (ng/ml), mean ± SD | 75.0 ± 205.02 | 13.5 ± 24.02 | 0.351 |
| Tumor location | | | 0.767 |
| Descending | 6 (11.3%) | 1 (7.1%) | |

| Cause of emergency surgery | NA | NA | |
| Perforation | 5 (35.7%) | | |
| Palpable mass on abdominal P/E | 4 (28.6%) | | |
| Severe abdomen pain | 3 (21.4%) | | |
| Mid to low rectal tumor location | 1 (7.1%) | | |
| Bleeding | 1 (7.1%) | | |

SP = stent placement group; EM = emergency operation group; SD = standard deviation; BMI = body mass index; CEA = carcino-embryonic antigen; NA = not applicable; P/E = physical exam.
analyzed under the approval of the Institutional Review Board in Korea University Anam Hospital. Patient demographics, tumor characteristics, operative and postoperative outcomes and 5-year survivals were compared between patients who had stent placement and those who underwent emergency surgery. SPSS version 20.0 (IBM, Armonk, NY, USA) was used, and the t-test and chi-square test were used for continuous and categorical variables, respectively. Survival analysis was conducted for patients except stage IV cancer patients using Kaplan–Meier analysis with log-rank test. p value less than 0.05 was considered statistically significant.

RESULTS

A total of 67 patients with left colon cancer and rectal cancer with obstruction were enrolled in our study. Stent placement was performed in 53 patients as a bridge to surgery. Stents effectively decompressed the proximal bowel in all patients, and there were no post–stent placement events such as bleeding or perforation. Fourteen patients received emergency surgery for various reasons (Table 1). Between the two groups, no significant differences were observed in age, sex, body mass index (BMI), preoperative carcino-embryonic antigen (CEA), tumor location, TNM stage, or tumor size.

The operative outcomes are outlined in Table 2. When comparing operative outcomes, there were significant differences in surgical approach, type of operation, and combined resection. Minimally invasive surgery (MIS) (88.6 vs. 42.9%, p<0.001) was higher in the stent placement (SP) as a bridge to surgery group, and combined resection (5.9 vs. 37.5%, p<0.001) was lower in the SP group. With regard to combined resection, four patients were treated due to invasion of pelvic organs, one patient had a gallbladder stone, and one patient had a pheochromocytoma of the adrenal grand. In the SP group, resection with anastomosis was performed in nearly all patients (92.5%) while in the emergency operation (EM) group,

| Table 2. Operative outcomes |
|-----------------------------|
|                              | SP (n=53) | EM (n=14) | p     |

| Operation time (min), mean±SD| 219.2±95.3 | 218.6±65.7 | 0.973 |
| Blood loss (ml), mean±SD    | 30.2±152.6 | 635.7±649.9 | 0.053 |

SP = stent placement group; EM = emergency operation group; SD = standard deviation; MIS = minimal invasive surgery. *Excluded abdominoperineal resection and Hartman’s procedure.
Hartmann’s procedure was most commonly performed (57.1%) \((p < 0.001)\). Only 50% of patients who underwent Hartmann’s procedure could be received the reversal operation later (the SP group vs. the EM group, 75 vs. 37.5%, respectively; \(p = 0.221\)). The two groups did not show a difference in diverting loop ileostomy, operative time, or the amount of blood loss. All diverting loop ileostomy were able to be repaired later.

No significant differences were demonstrated in histopathologic results between the two groups (Table 3). Postoperative courses and adjuvant treatment are shown in Table 4. There were no significant differences between the two groups with regard to postoperative hospital stay (16.7 vs. 14.9 days, \(p = 0.103\)), days to flatus (2.2 vs. 2.4 days, \(p = 0.809\)), days to resumption of diet (3.3 vs. 5.4 days, \(p = 0.102\)), postoperative complications (17.0 vs. 7.1%, \(p = 0.870\), or the types of adjuvant chemotherapy (\(p = 0.901\)).

We compared long-term outcomes for patients except for stage IV patients. Five-year overall survival (OS) rates were 96.0 and 77.8% \((p = 0.311)\) in the SP and EM groups respectively (Fig. 1). The median survival time was 65.6 months in the SP group and 69.2 months in the EM group. Five-year OS rates were 100.0% in the SP group and 75.0% in the EM group for stage II \((p = 0.448)\), and 96.0% in the SP group and 77.8% in the EM group for stage III \((p = 0.560)\) (Fig. 1). Five-year disease-free survival (DFS) rates for local recurrence in the SP and EM groups were 90.0 and 88.9% \((p = 0.904)\). Five-year DFS rates for local recurrence were 83.3% in the SP group and 100.0% in the EM group for stage II \((p = 0.564)\), and were 100.0% in the SP group and 75.0% in the EM group for stage III \((p = 0.750)\) (Fig. 2). And, five-year DFS rates for systemic recurrence in the SP and EM groups were 92.9 and 66.7% \((p = 0.219)\). Five-year DFS rates for systemic recurrence were 93.4% in the SP group and 80% in the EM group for stage II \((p = 0.469)\), and were 83.3% in the SP group and 58.3% in the EM group for stage III \((p = 0.922)\) (Fig. 3).

**DISCUSSION**

In our study, we found the minimally invasive surgery was performed actively in the SP group and the percentage of resection and anastomosis was higher compared with the use of Hartmann’s operation in the SP group. We observed comparable postoperative progress and long-term results.
between the SP and EM groups.

Hartmann’s operation is generally performed as a temporary method to stabilize left-sided colonic emergencies including colonic obstruction, perforation, bleeding or anastomotic leakage that are not appropriate for primary anastomosis. The subsequent restoration of bowel continuity is advisable for better quality of life, but it may be technically challenging for

**Fig. 1.** Comparison of 5-year overall survival in patients with malignant colonic obstruction treated with stent as a bridge to surgery or emergency surgery only. (A) All stage, (B) Stage II, (C) Stage III. SP = stent placement group; EM = emergency operation group.

**Fig. 2.** Comparison of 5-year disease free survival for local recurrence in patients with malignant colonic obstruction treated with stent as a bridge to surgery or emergency surgery only. (A) All stage, (B) Stage II, (C) Stage III. SP = stent placement group; EM = emergency operation group.
surgeons. In addition, the reversal of Hartmann’s operation has considerable morbidity and mortality including postoperative leakage, stricture, bleeding, and wound infections. For this reason, re-anastomosis is performed in only 55 to 60% of patients who receive Hartmann’s operation.\textsuperscript{14-18} Our study also showed the rate of Hartmann’s reversal operation was 75% in the SP group, 37.5% in the EM group, and 50% in total. Therefore, the lower rate of Hartmann’s operation in the stent placement patients may positively influence long-term quality of life, as seen in our study.

Most of the SP group patients were able to have minimally invasive surgery, such as laparoscopic or robotic surgery. The availability of laparoscopic surgery may be affected by various factors, and it is difficult to perform laparoscopic surgery in cases of severe ileus of the proximal bowel due to obstruction of the distal colon. For these reasons, the proportion of patients who underwent surgery using MIS was likely higher in the SP group because of effective proximal bowel decompression by stenting. As it is well known, laparoscopic surgery has great something compared to open surgery including reduced postoperative pain, early recovery, faster resumption of diet, and improved cosmesis.\textsuperscript{19,20} The SP group patients were able to continue these advantages as well. In our study, there was one adrenalectomy as a combined operation due to pheochromocytoma. Pheochromocytoma surgery is high risk and requires intensive preparation before surgery related to hormone secretion. In these patients, the risk of emergency surgery is much higher than in well-planned, elective surgery. In this case, effective stent placement allowed elective colectomy with adrenalectomy to be performed safely. If the patient has poor general condition or a critical co-morbidity and is at risk of deteriorate condition under general anesthesia such as thyrotoxic crisis, called thyroid storm which can cause a hypertensive crisis, stenting may allow a period for recovery and improvement before elective surgery to reduce morbidity and mortality compared with emergency surgery.\textsuperscript{21,22}

Contrary to our expectations, there were no significant differences in postoperative outcomes between the SP and EM groups. We apply the enhanced recovery after surgery (ERAS) protocol to patients undergoing laparoscopic and open surgery both in our institution.\textsuperscript{23,24} The shared protocol may explain why the EM group, which included more patients who underwent open surgery, did not show inferior results in terms of postoperative diet resumption or hospital stay compared with the SP group.

Recently, reports have raised the possibility that stent insertion increases local cancer recurrence due to subclinical perforation during implantation. Concern for cancer cells causing metastasis along peripheral blood vessels with worsened survival has been suggested. Kim et al.\textsuperscript{25} reported that SEMS insertion had an adverse effect on the five-year overall survival rate (SEMS group vs. emergency surgery group, 38.4 vs. 65.6%, respectively: \(p=0.025\)) and the five-year disease-free survival rate (SEMS group vs. emergency surgery group, 12.0 vs. 24.0%, respectively: \(p=0.219\)).

**Fig. 3.** Comparison of 5-year disease free survival for systemic recurrence in patients with malignant colonic obstruction treated with stent as a bridge to surgery or emergency surgery only. (A) All stage, (B) Stage II, (C) Stage III. SP = stent placement group; EM = emergency operation group.
surgery group, 48.3 vs. 75.5%, respectively; $p=0.024$). On the other hand, long-term outcomes were not significantly different between the two groups in our study. Five-year overall survival was 96.0 and 77.8% ($p=0.311$) in the SP group and EM groups respectively. Five-year disease-free survival for local recurrence in the SP and EM groups were 90.0 and 88.9% ($p=0.904$). Similarly, Saida et al.\(^{26}\) reported that long-term outcomes did not significantly differ and the five-year overall survival rate was 40% in the expandable metallic stent group and 44% in the emergency operation group. Choi et al.\(^{27}\) also showed no significant difference in long-term prognosis between two groups in either the five-year disease-free survival for recurrence (SEMS group vs. emergency surgery group, 79.6 vs. 70.2%, $p=0.218$) or the five-year overall survival rate (SEMS group vs. emergency surgery group, 97.8 vs. 94.3%, $p=0.469$).

To date, no study has been published that definitively shows that either approach is worse than the other considering the institutional and technical bias. That being said, stent placement for malignant obstruction has found a solid home for the surgical treatment option of malignant obstruction so far. However, there remains debate regarding the effect of stent insertion for long-term oncologic outcomes, and future studies with long-term follow-up result including CReST (ColoRectal Stenting Trial) is expected.

Our study has a few limitations. First, our study is a retrospective analysis and suffers from selection bias. We did not compare the results from randomized patients following stent insertion or emergency surgery, and instead reviewed the results of patients who were not able to undergo stent placement and underwent emergency surgery. In addition, the decision and ability to place stents is somewhat subjective and can differ across institutions. The success rate of stent placement in our study was 100%, and this is higher than the 86~98% generally reported.\(^{28,29}\) This suggests that there are well-trained endoscopists at our hospital but also could reflect that stent insertion as a bridge to surgery was more narrowly considered as an option. Finally, this study reflects a small amount of single-center data and a relatively small patient group. That is due to the definition for total obstruction in the enrolled patients.

In conclusion, colonic stenting can be used safely as a bridge to elective surgery as an alternative to emergency surgery in patients with left colon and rectal cancer obstruction. Stent placement as a bridge to surgery demonstrated comparable results with emergency surgery with regard to long-term oncologic outcomes.
