ABSTRACT

Combined anti-retroviral therapeutic drugs effectively increase the lifespan of HIV-1-infected individuals who then have a higher prevalence of HAND (HIV-1 associated neurocognitive disorder). Soluble factors including HIV-1 proteins released from HIV-1-infected cells have been implicated in the pathogenesis of HAND, and particular attention has been paid to the HIV-1 Tat (transactivator of transcription) protein because of its ability to directly excite neurons and cause neuronal cell death. Since HIV-1 Tat enters cells by receptor-mediated endocytosis and since endolysosomes play an important role in neuronal cell life and death, we tested here the hypothesis that HIV-1 Tat neurotoxicity is associated with changes in the endolysosome structure and function and also autophagy. Following the treatment of primary cultured rat hippocampal neurons with HIV-1 Tat or as controls mutant-Tat or PBS, neuronal viability was determined using a triple staining method. Preceding observations of HIV-1 Tat-induced neuronal cell death, we observed statistically significant changes in the structure and membrane integrity of endolysosomes, endolysosome pH and autophagy. As early as 24 h after HIV-1 Tat was applied to neurons, HIV-1 Tat accumulated in endolysosomes, endolysosome morphology was affected and their size increased, endolysosome membrane integrity was disrupted, endolysosome pH increased, specific activities of endolysosome enzymes decreased and autophagy was inhibited, as indicated by the significant changes in three markers for autophagy. In contrast, statistically significant levels of HIV-1 Tat-induced neuronal cell death were observed only after 48 h of HIV-1 Tat treatment. Our findings suggest that endolysosomes are involved in HIV-1 Tat-induced neurotoxicity and may represent a target for therapeutic intervention against HAND.

Key words: autophagy, endosome, HIV-1 Tat, lysosome, neuronal cell death, pH.

INTRODUCTION

More than 40 million people worldwide are infected with HIV-1, and combined anti-retroviral therapeutic drugs have effectively increased the lifespan of people living with HIV. Increased as well is the prevalence of HAND (HIV-1-associated neurocognitive disorder) with recent epidemiological studies indicating that the prevalence of HAND in the U.S.A. is greater than 50% of HIV-1-infected people (Ellis et al., 2010; Heaton et al., 2010). Clinically, HAND represents a set of conditions ranging from subtle neuropsychological impairments to profoundly disabling HIV-associated dementia. Although the underlying mechanisms for HAND pathogenesis are not fully understood, soluble factors including HIV-1 viral products and pro-inflammatory mediators released from the infected glia and monocytes have been implicated (Ghafouri et al., 2006; King et al., 2006; Wallace 2006; Ances and Ellis, 2007). Among the viral products, HIV-1 Tat (transactivator of transcription) protein has been shown to be neuroexcitatory and neurotoxic, and it continues to be implicated as a causative agent in HAND (Sabatier et al., 1991; Weeks et al., 1995; Haughey et al., 1999; Nath et al., 2000; Perez et al., 2001; King et al., 2006; Buscemi et al., 2007b; Agrawal et al., 2012).

HIV-1 Tat is a non-structural transcriptional regulator essential for the replication of HIV-1. The first exon of HIV-1 Tat encodes the first 72 amino acids and the second exon encodes another 14–32 amino acids. Tat1–72 is sufficient for transactivation, which requires the arginine-rich domain of Tat and it continues to be implicated as a causative agent in HAND (Sabatier et al., 1991; Weeks et al., 1995; Haughey et al., 1999; Nath et al., 2000; Perez et al., 2001; King et al., 2006; Buscemi et al., 2007b; Agrawal et al., 2012).

Pregnant dams (embryonic day 18) were killed by asphyxiation with CO₂. The fetuses were removed, decapitated, and meninges-free hippocampi were isolated, trypsinized and plated on to 35-mm poly-d-lysine-coated glass-bottom tissue culture dishes. Neurons were grown in the Neurobasal™ medium with l-glutamine, antibiotic/antimycotic and B27 supplement, and were maintained at 37°C and 5% CO₂ for 10–14 days at which time they were used for the experimentation. Typically, the purity of the neuronal cultures was greater than 95% as determined by neuronal staining with mouse anti-NeuN or goat anti-MAP2 (microtubule-associated protein 2) antibodies (Millipore); astrocytes were identified using a mouse anti-GFAP (glial fibrillary acidic protein) antibody (Sigma). Neurons were treated either with HIV-1 Tat1–72 (100 nM, a gift from Dr Avindra Nath, Johns Hopkins University School of Medicine, Baltimore, MD, U.S.A.), mutant Tat (Tat31–61, 100 nM) or PBS as vehicle.

**Neuronal cell viability assay**

Neuronal cell viability was determined using a triple staining method as described previously (Buscemi et al., 2007). Neurons were stained with Hoechst 33342 (10 μg/ml), ethidium homodimer-1 (4 μM) and calcine (1 μg/ml). Hoechst 33342, which labels DNA, was used as a marker for identifying condensed nuclei characteristic of apoptotic cell death. Cells dead or dying as a result of loss of membrane integrity were unable to exclude ethidium homodimer-1 dye. Cells were considered viable when cytoplasm was stained with green fluorescence after the cleavage of the non-fluorescent calcine AM (acetoxyethyl ester) to calcine. Fields were chosen randomly and at least five images from five separate fields of culture dishes for every experimental condition were taken with our Axiovert 200 M fluorescence microscope (Zeiss) and filter-based imaging system. The number of dead or dying neurons (ethidium-labelled red nuclei and blue-condensed nuclei without green cytoplasmic staining) and total neuron numbers were counted manually. More than 900 neurons were counted per experimental condition. Neuronal viability was reported as a percentage of total neurons.

**Measurement of endolysosome pH**

Endolysosome pH was measured using a ratio-metric lysosome pH indicator dye (LysoSensor Yellow/Blue DND-160 from Invitrogen); a dual excitation dye that permits pH measurements in acidic organelles independently of dye concentration. Neurons were loaded with 2 μM LysoSensor for 5 min at 37°C. Light emitted at 520 nm in response to λex at 340 and 380 nm was measured for 20 ms every 30 s using a filter-based imaging system (Zeiss). The ratios of light excited at 340/380 nm and emitted at 520 nm were converted to pH using a calibration curve established using 10 μM of the H⁺/Na⁺ ionophore monensin, and 20 μM of the H⁺/K⁺ ionophore nigericin dissolved in 20 mM Mes, 110 mM KCl, and 20 mM NaCl adjusted to pH 3.0–7.0 with HCl/NaOH.

**MATERIALS AND METHODS**

**Hippocampal neuron primary cultures**

Primary cultures of hippocampal neurons were prepared from embryonic day 18 Sprague–Dawley rats as described previously (Buscemi et al., 2007) using a protocol approved by the University of North Dakota Animal Care and Use Committee adherent with the Guide for the Care and Use of Laboratory Animals (NIH publication number 80–23). Pregnant dams (embryonic day 18) were killed by given how avidly HIV-1 Tat binds to proteins and cells (Westendorp et al., 1995; Xiao et al., 2000). HIV-1 Tat can be transported across the blood–brain barrier from the systemic circulation (Kim et al., 2003; Banks et al., 2005), can be secreted by infected macrophages and microglia, and has been detected in brain of patients with HIV-1-associated dementia (Westendorp et al., 1995; Ellis et al., 2000; Nath, 2002).

HIV-1 Tat enters neurons via receptor-mediated endocytosis involving CD26 (Gutheil et al., 1994), CXCR4 (CXC chemokine receptor type 4) (Xiao et al., 2000), heparin sulphate proteoglycans (Tyagi et al., 2001) and LDL (low-density lipoprotein) receptor-related proteins (Liu et al., 2000; Vendeville et al., 2004; King et al., 2006; Deshmane et al., 2011). Endocytosis is a very rapid and early event, which results in the accumulation of HIV-1 Tat in endolysosomes from which it can be released into the cytoplasm and uptaken into the nucleus (Vives et al., 1997; Liu et al., 2000; Caron et al., 2004), most probably through the mechanisms involving the high H⁺ gradient maintained by vacuolar H⁺-ATPase (Vendeville et al., 2004). The endolysosome system is very dynamic, and lysosomes and other acidic sub-cellular compartments are involved in endocytosis and autophagy (Jeyakumar et al., 2005; Nixon and Cataldo, 2006). Endosomes and lysosomes process proteins and other materials that are endocytosed, whereas autophagy predominantly process cytosolic proteins.

Neurons are highly polarized long-lived post-mitotic cells, which possess an elaborate endolysosome system critical for the maintenance of neuronal function (Nixon and Cataldo, 1995, 2006). Increasingly, endolysosome dysfunction has been implicated in neuronal damage and in the pathogenesis of a variety of neurological disorders including AD (Alzheimer’s disease), Parkinson’s disease and HAND (Gelman et al., 2005; Spector and Zhou, 2008; Zhou and Spector, 2008). Here, we tested the hypothesis that HIV-1 Tat induces neuronal damage by affecting the structure and function of endolysosomes. We report that HIV-1 Tat enlarged endolysosomes, disrupted endolysosome membrane integrity, elevated endolysosome pH, decreased specific activities of endolysosome enzymes and inhibited autophagy. Our findings suggest that the disturbed structure and function of endolysosomes play an early and important role in HIV-1 Tat-induced neuronal damage.
Living cell imaging

The morphology of endolysosomes in living neurons was determined using a Lysotracker dye. After treatments, neurons were loaded with Lysotracker Red DND-99 (50 nM, Invitrogen) and calcein AM (1 µg/ml, Invitrogen) for 30 min at 37°C. Fields were chosen at random and at least five images from every experimental condition were acquired by confocal microscopy (Olympus). The sizes of endolysosomes (Lysotracker) were analysed with the particle-analysing program in Image J software. For measurement of Tat endocytosis, neurons were incubated with FITC-Tat (100 nM, AnaSpec) for 1 day at 37°C, followed by loading of Lysotracker Red DND-99 (50 nM) and Hoechst 33342 (10 µg/ml) for an additional 30 min. Images were taken with an Axiovert 200 M fluorescence microscope (Zeiss).

Immunocytochemistry

Neurons were fixed with cold methanol (−20°C) for 10 min, washed with PBS, blocked with 5% goat serum, and incubated overnight at 4°C with primary antibodies targeting EEA1 (early endosome antigen 1; 1:500, rabbit polyclonal, Santa Cruz) or LAMP1 (lysosome-associated membrane protein-1; 1:500, rabbit polyclonal, Sigma). After washing with PBS, neurons were incubated with Alexa Fluor® 546-conjugated goat anti-rabbit antibodies (Invitrogen). Neurons were examined by confocal microscopy (Olympus). Controls for specificity included staining neurons with primary antibodies without fluorescence-conjugated secondary antibodies (background controls) and staining neurons with only secondary antibodies.

Endolysosome membrane permeability

Endolysosome membrane permeability was determined by measuring the leakage of endolysosome fluorescent dye Lucifer Yellow CH (Invitrogen). Neurons were incubated with Lucifer Yellow (100 µg/ml) for 16 h, followed by incubation with Tat at 37°C for 1 and 2 days. Levels of dye inside of neurons were detected by confocal microscopy (Olympus).

Immunoblotting

Neurons were lysed with RIPA buffer (Pierce) containing protease inhibitor cocktail (Sigma). After centrifugation (14000 g for 10 min at 4°C), supernatants were collected, and protein concentrations were determined with a DC protein assay (Bio-Rad). Equal amounts of proteins (10 µg) were separated by SDS/12% PAGE, and, following transfer, PVDF membranes (Millipore) were incubated overnight at 4°C with anti-EEA1 (1:1000, Santa Cruz Biotechnology), anti-LAMP1 (1:1000, Sigma), anti-acid phosphatase (1:1000, mouse monoclonal, Abcam), anti-cathepsin B (1:500, mouse monoclonal, Sigma), anti-cathepsin D (1:1000, mouse monoclonal, Sigma), anti-LC3 (light chain 3) b (1:1000, rabbit polyclonal, Abcam), anti-Atg5 (autophagy-related gene-5; 1:2000, mouse monoclonal, Millipore) or anti-p62 (1:1000, rabbit polyclonal, Sigma) antibodies; anti-β-actin (1:10000, mouse monoclonal, Abcam) antibody was used as a gel-loading control. The blots were developed with enhanced chemiluminescence, and bands were visualized and analysed by LabWorks 4.5 software on a BioSpectrum® imaging System (UVP). Quantification was performed by densitometry and the results were analysed as total integrated densitometric volume values (arbitrary units).

Measurement of activities of endolysosome enzymes

Enzyme activities of acid phosphatase were determined using an acid phosphatase assay kit (Sigma); a luminescence-based assay that uses 4-nitrophenyl phosphate as substrate (Chen et al., 2010). Enzyme activities of cathepsins D and B were determined using assay kits (BioVision); fluorescence-based assays that used cathepsin D or cathepsin B preferred substrates labelled with MCA (Chen et al., 2010). Enzyme activities were expressed as absorbance per 10 µg of protein. Specific activities of each enzyme were expressed as a ratio of enzyme activity to protein levels as determined by immunoblotting.

Statistical analysis

All data were expressed as means ± S.E.M. Statistical significance for multiple comparisons was determined by one-way ANOVA plus a Tukey post hoc test. P<0.05 was considered to be statistically significant.

RESULTS

In order to compare the effects of HIV-1 Tat on neuronal damage and the structure and function of endolysosomes, we needed to first determine the time course and extent to which HIV-1 Tat decreased neuronal viability. HIV-1 Tat induced significant amounts of neuronal cell death starting from 48 h of treatment (n=5, P<0.05) with a maximum of 50% neuronal cell death (n=5, P<0.001) after the treatment for 96 h (Figure 1). These data were consistent with previous studies that have shown similar neurotoxic effects of HIV-1 Tat (Kruman et al., 1998; Haughey et al., 1999; Bonavia et al., 2001; Aksenov et al., 2003; Buscemi et al., 2007; Eugenin et al., 2007). No statistically significant increases in neuronal cell death were observed with either mutant TatΔ21−61 or PBS, consistent with previous reports that this deletion mutant of Tat is not directly toxic to neurons (Buscemi et al., 2007).

In neurons and other cells, HIV-1 Tat uses receptor-mediated endocytotic mechanisms (Liu et al., 2000; Vendeville et al., 2004; King et al., 2006) to enter cells where HIV-1 Tat accumulates first in endolysosomes. Since the basic region of
amino acids 49–57 of HIV-1 Tat is required for binding to membrane receptor proteins (Sabatier et al., 1991) and exerting its neurotoxic effects (Weeks et al., 1995), we used a FITC-labelled Tat

**Figure 1** HIV-1 Tat-induced neuronal cell death in a time-dependent manner

Significant amounts of neuronal cell death were observed after 2-day incubation with HIV-1 Tat (100 nM) and reached a maximal level of 50% cell death by the fourth day. No significant neuronal cell death was observed in neurons treated with either mutant Tat or PBS ($n=5$, *P*<0.05 and ***P*<0.001).

**Figure 2** HIV-1 Tat–altered the structure of neuronal endolysosomes

(A) HIV-1 Tat is accumulated in endolysosomes of primary cultured neurons. FITC-labelled Tat$_{47-57}$ peptide (100 nM, green) was co-localized with endolysosomes (red, LysoTracker) and DAPI (4',6-diamidino-2-phenylindole; blue) was used for staining nuclei. Bar=50 μm. (B) Live cell imaging showed that HIV-1 Tat (100 nM) treatment increased the sizes of neuronal endolysosomes. LysoTracker (red) was used to identify endolysosomes, and calcine AM (green) was used to stain living cells (top panel), and the sizes of endolysosomes were quantified with Image J software. HIV-1 Tat-enlarged endosomes as identified with EEA1 staining (middle panel), HIV-1 Tat-enlarged lysosomes as identified with LAMP1 staining (bottom panel). (C) Quantification of the top panel of (B) showed that HIV-1 Tat (100 nM) treatment for 1 and 2 days increased significantly the size of neuronal endolysosomes ($n=15$).
The observation that HIV-1 Tat alters endolysosome morphology led us to determine next the extent to which HIV-1 Tat-affected endolysosome function. Since pH is critical for endolysosome function, we determined the extent to which HIV-1 Tat-affected endolysosome pH using LysoSensor dye, which permits ratio-metric assessment of pH changes in acidic organelles. We found that HIV-1 Tat, but not mutant Tat treatment for 1 or 2 days elevated significantly (n=20, P<0.001) endolysosome pH in cultured hippocampal neurons (Figure 3). As endolysosome pH affects endolysosome enzyme activity, we next determined the protein levels and activity of endolysosome enzymes as evaluations of endolysosome function. Treatment of neurons with HIV-1 Tat for 1 or 2 days increased significantly protein levels of the endolysosome enzymes acid phosphatase (Figure 4A, n=4, P<0.01 at 1 day and n=4, P<0.05 at 2 days), cathepsin B (Figure 4C, n=4, P<0.05) and cathepsin D (Figure 4E, n=4, P<0.01 at 1 day and P<0.05 at 2 days). However, the specific activity levels of

Figure 3 HIV-1 Tat–elevated endolysosome pH in primary cultured neurons
Endolysosome pH was measured ratio-metrically using LysoSensor dye. HIV-1 Tat (100 nM) treatment for 1 and 2 days elevated significantly endolysosome pH (n=20).

Figure 4 HIV-1 Tat–altered the expression and activity of endolysosome enzymes
(A, C, E) HIV-1 Tat (100 nM) increased protein levels of acid phosphatase (ACP), cathepsin B (Cat B), and cathepsin D (Cat D). Representative Western blots and quantitative data from each of the enzymes are shown (n=4). Actin was used as a loading control. (B, D, F) HIV-1 Tat (100 nM) decreased significantly specific enzyme activity of ACP, Cat B and Cat D (n=4).
Acid phosphatase (Figure 4B), cathepsin B (Figure 4D) and cathepsin D (Figure 4F) were decreased significantly \((n=4, P<0.001)\) in HIV-1 Tat-treated cultures.

Endolysosome dysfunction has been implicated in initiating stress pathways that lead to cellular dysfunction and death (Roberg and Ollinger, 1998; Turk et al., 2002; Guicciardi et al., 2004; Kroemer and Jaattela, 2005; Kurz et al., 2008). Here, we determined the extent to which HIV-1 Tat-affected endolysosome membrane integrity using Lucifer Yellow dye (Yang et al., 1998). We found that while control neurons displayed a discrete punctate pattern of perinuclear fluorescent staining (Figure 5), HIV-1 Tat-treated neurons displayed increased endolysosome membrane leakage as evidenced by diffuse fluorescent staining (Figure 5) in the cytoplasm.

Endolysosomes also function to control autophagy, a process important for normal physiological functions of neurons. Dysfunctions in autophagy have been implicated in the pathogenesis of a variety of neurodegenerative disorders (Wong and Cuervo, 2010) including HAND (Alirezaei et al., 2008b; Alirezaei et al., 2008a; Spector and Zhou, 2008; Zhou and Spector, 2008; Zhu et al., 2009; Zhou et al., 2011). Based on the findings that HIV-1 Tat disrupts autophagy in immune cells (Van Grol et al., 2010), we determined the extent to which HIV-1 Tat-affected autophagy in primary cultured hippocampal neurons. Three markers were used to evaluate the status of autophagy; MAP1 LC3 which regulates the initiation process of autophagy, Atg5 which regulates the elongation process of autophagy, and p62 which inhibits autophagy. We found that HIV-1 Tat treatment decreased significantly protein levels of LC3 (Figure 6A, \(n=4, P<0.05\) at 2 day treatment) and Atg5 (Figure 6B, \(n=4, P<0.05\) at 1 day and \(P<0.01\) at 2 days treatment), but increased significantly protein levels of p62 (Figure 6C, \(n=4, P<0.05\) at 1 and 2 days treatment).

**DISCUSSION**

Combined highly active anti-retroviral therapeutic drugs have increased dramatically the lifespan of people now living with AIDS. However, this increased lifespan is accompanied by increased prevalence of HAND, which affects up to 50% of people with HIV-1 infection (Ellis et al., 2010; Heaton et al., 2010; Van Grol et al., 2010).
The underlying mechanisms for HAND pathogenesis are not fully understood, but one mechanism that appears to be important yet relatively understudied is the involvement of endolysosomes. Disturbed endolysosomes have been noted in brain of HIV-1-infected individuals (Gelman et al., 2005; Spector and Zhou, 2008; Zhou and Spector, 2008), but the mechanisms for these pathological observations are not known. Since neurons are long-lived post-mitotic cells with extreme polarity, they possess an elaborate endolysosome system that contains hydrolases that degrade macromolecules, high concentrations of readily releasable calcium (Christensen et al., 2002; Moreno and Docampo, 2009; Patel and Docampo, 2010), and high concentrations of potentially redox-active iron (Brun and Brunk, 1970; Kidane et al., 2006). When dysfunctional, endolysosomes can contribute to altered calcium homoeostasis (Korkotian et al., 1999; Pelled et al., 2005; Lloyd-Evans et al., 2008) and increased oxidative stress (Pivtoraiko et al., 2009). Disruptions in endolysosome functions perturb numerous cellular functions and can ultimately result in the initiation of cell death pathways (Kroemer and Jaattela, 2005; Kurz et al., 2008). Therefore it is of potential significance to further understand the pathogenesis of HAND that we found that HIV-1 Tat-enlarged endolysosomes, elevated endolysosome pH, decreased specific activities of endolysosome enzymes, disrupted endolysosome membrane integrity and inhibited autophagy, all of which occurred prior to significant increases in HIV-1 Tat-induced neuronal cell death. Thus, the altered structure and function of endolysosomes could underlie, at least in part, the pathogenesis of HAND.

HIV-1 Tat protein continues to be implicated in the pathogenesis of HAND, in part, because there is significant neuronal dysfunction even though neurons are not infected by HIV-1 virus (Nuovo et al., 1994; Merino et al., 2011). HIV-Tat has been shown to, for example, activate NMDA (by HIV-1 virus (Nuovo et al., 1994; Merino et al., 2011). HIV-neuronal dysfunction even though neurons are not infected pathogenesis of HAND, in part, because there is significant

Alterations in the structure and function of neuronal endolysosomes have been noted in HAND (Gelman et al., 2005; Spector and Zhou, 2008; Zhou and Spector, 2008) and because HIV-1 Tat can accumulate in neuronal endolysomes, we determined the extent to which HIV-1 Tat disturbed neuronal endolysosome structure and function. We demonstrated that HIV-1 Tat disturbed endolysosomes and inhibited autophagy as indicated by changes to marker proteins. There exist three types of autophagy in cells: macroautophagy, microautophagy and chaperone-mediated autophagy. As the best-studied type of autophagy, macroautophagy includes three stages such as autophagosome membrane origination, autophagosome formation and autolysosome formation. Accordingly, we focused our studies on the effects of HIV-1 Tat on macroautophagy using three markers: LC3 which mediates the initiation process of (Winslow and Rubinsztein, 2008), Atg5 which drives the elongation process of (Mizushima, 2007), and p62 which inhibits autophagy (Ichimura and Komatsu, 2010; Bjorkoy et al., 2005; Pankiv et al., 2007). Our findings suggest that HIV-1 Tat directly affects the morphology and function of endolysosomes and autophagy.

Low pH is critical for the degradation of internalized materials, the trafficking and fusion of endolysosomes and the formation of autophagy (Marshansky and Futai, 2008; Ravikumar et al., 2010; Williamson et al., 2010). Thus, central to the observed changes might be the ability of HIV-1 Tat to elevate endolysosome pH. Our observations of elevated endolysosome pH could help to explain alterations in the digestive capability of endolysosomes as evidenced by decreased specific activities of three different endolysosome enzymes, which results in increased accumulation of internalized material thus altering the structure and size of endolysosomes. In addition, elevation of endolysosome pH could result in alterations in the trafficking and fusion of endolysosomes (Hart and Young, 1991; Saftig and Klumperman, 2009). Furthermore, elevation of endolysosome pH could result in alterations in the fusion of autophagosomes with lysosomes (Kawai et al., 2007) thus inhibiting autophagy. Together, elevation of endolysosome pH could exaggerate neuronal injury and degeneration (Wong and Cuervo, 2010), and contribute directly to HIV-1 Tat-induced neurotoxicity.

Although the underlying mechanisms whereby HIV-1 Tat elevates endolysosome pH are unknown, the arginine-rich domain of HIV-1 Tat between amino acid residues 49 and 57 could be responsible for HIV-1 Tat-induced elevation of endolysosome pH because a series of other arginine-rich peptides including penetratin, an amino acid domain from the Antennapedia protein (sequences 43–58) of Drosophila, a flock house virus coat peptide (sequences 35–49) and oligo-arginines (R9) all have the ability to elevate endolysosome
Furthermore, disrupted endolysosome membrane integrity per se could lead to neuronal dysfunction and ultimately cell death because the increased endolysosome membrane permeability occurs in several models of apoptosis (Roberg and Ollinger, 1998; Turk et al., 2002; Guicciardi et al., 2004; Kroemer and Jaattela, 2005; Kurz et al., 2008) and is an early event in the apoptotic cascade that precedes destabilization of mitochondrion and caspase activation (Kroemer and Jaattela, 2005; Kurz et al., 2008). These potential mechanisms warrant further investigation.

Our finding that HIV-1 Tat disturbed the structure and function of endolysosomes in primary cultured neurons prior to any significant increase in HIV-1 Tat-induced neurotoxicity suggests that the effects of HIV-1 Tat on endolysosomes may cause considerable neuronal dysfunction. Further elucidation of the involvement of endolysosomes in HAND might lead to the design of novel therapeutic strategies, including blocking the entry of HIV-1 Tat into endolysosomes and blocking HIV-1 Tat-induced elevation of endolysosome pH.
