For rare events, path probabilities often concentrate close to a predictable path, called instanton. First developed in statistical physics and field theory, instantons are action minimizers in a path integral representation. For chaotic deterministic systems, where no such action is known, shall we expect path probabilities to concentrate close to an instanton? We address this question for the dynamics of the terrestrial bodies of the Solar System. It is known that the destabilization of the inner Solar System might occur with a low probability, within a few hundred million years, or billion years, through a resonance between the motions of Mercury and Jupiter perihelia. In a simple deterministic model of Mercury dynamics, we show that the first exit time of such a resonance can be computed. We predict the related instanton and demonstrate that path probabilities actually concentrate close to this instanton, for events which occur within a few hundred million years. We discuss the possible implications for the actual Solar System.

Rare events can be very important if their large impact compensate for their low probability. From a dynamical perspective, when conditioned on the occurrence of a rare event, path probabilities often concentrate close to a predictable path, called instanton. This is a key and fascinating property for the dynamics of rare events and of their impact [1], which was first observed in statistical physics, for the nucleation of a classical supersaturated vapor [2]. Soon after, a similar concentration of path probabilities has been studied in gauge field theories [3, 4], for instance for the Yang-Mill theory. Instantons continue to have number of applications in modern statistical physics, for instance to describe excitation chains at the glass transition [5], reaction paths in chemistry [6], escape of brownian particles in soft matter [7], MHD [8] and turbulence [9–13], among many other examples. Moreover, a large effort has been pursued to develop dedicated numerical approaches to compute instantons [14]. Inspired by the earlier works, action minimization have found a rigorous mathematical treatment, through the Freidlin-Wentzell large deviation theory [15] of ordinary differential equations with small noises [16].

In all those classical or quantum applications, instantons appear as action minimizers, for a saddle point evaluation of a path integral. The basic property of the instanton phenomenology is that, conditioned on the occurrence of a rare event, path probabilities concentrate close to a predictable path. Fig. (1) gives an illustration of this property for a particle in a bistable potential. Shall we expect this phenomenology to be valid for systems for which no action exist in the first place, for instance chaotic deterministic systems? The main aim of this work is to open this fascinating question for a paradigmatic problem in the history of physics: the dynamics of the Solar System. Shall we expect an instanton phenomenology for rare events that shaped or will shape the Solar System history?

The discovery that our solar system is chaotic with a Lyapunov time of about 5 million years [17–19] has disproved the previous belief that planetary motion would be predictable with any desired degree of precision. On the contrary, chaotic motion sets an horizon of predictability of a few tens of million years for the solar system. Even more striking has been the discovery that the solar system is only marginally stable, which means that about 1% of the trajectories lead to collisions between planets, or between planets and the Sun within 5 billion years [20].

As shown numerically, chaotic disintegration of the inner solar system (i.e. the four terrestrial planets) always happens through a resonance between the motion of Mercury’s and Jupiter’s perihelia [20–23], related to a large increase in Mercury’s eccentricity. Stochastic perturbation to planetary motion exists, for instance through the chaotic motion of the asteroid belt, but is too weak to be responsible for the rare destabilizations of the inner solar system [22, 24]. Instead, stochasticity in the solar system appears because of the development of internal deterministic chaos [22].

Does an instanton phenomenology exist for the rare destabilization of the Solar System? Our first result will be obtained within a simplified model of Mercury’s dy-
namics [25]. We predict for this model the probability distribution of the first destabilization time, the instanton paths, and check the instanton phenomenology.

The secular dynamics describes the planetary motion averaged over fast orbital motion. The secular dynamics Hamiltonian is

$$H(I, \Phi) = H_{\text{int}}(I) + \sum_{k \in \mathbb{Z}^6} A_k(I) \cos(k \cdot \Phi), \quad (1)$$

where $(I, \Phi)$ is the canonical set of Poincaré action-angle variables for the 8 planets, $k$ is a vector of integers, and the coefficients $A_k$ are functions of the action variables only (see e.g. [26] for the explicit expression of $H$ to forth order in planetary eccentricities and inclinations). We will study Mercury’s possible destabilization in the framework of a simplified model proposed by Batygin and col. [25]. This model should be seen as a minimal model retaining the relevant interactions leading to destabilization of the inner Solar System but is not expected to describe quantitatively the inner Solar System.

The approximations of [25] consist in keeping only the degrees of freedom of a massless Mercury in the Hamiltonian (1), and replace all other action-angle variables by the coefficients in Eq. (2) are given in appendix A.

A slow variable for Mercury’s dynamics: We first show how a slow variable can be built from the dynamics defined by the Hamiltonian (2). In Eq. (2), $H_{\text{int}}$ only depends on the actions. Would the total Hamiltonian be reduced to this part, Mercury’s dynamics would be integrable. The actions would be constant and the canonical angles would simply grow linearly with time according to Hamilton’s equations

$$\begin{align*}
\dot{\varphi}(t) &= \frac{\partial H_{\text{int}}}{\partial J} = -g_1(I, J) + g_5, \\
\dot{\psi}(t) &= \frac{\partial H_{\text{int}}}{\partial I} = -s_1(I, J) + s_2.
\end{align*} \quad (3)$$

The fundamental frequencies $g_1(I, J)$ and $s_1(I, J)$ describe Mercury’s perihelion precession at frequency $g_1$, and its orbital plane oscillations with respect to the invariant reference plane, at frequency $s_1$. For the model (2), $g_1$ value is about $5.7''/\text{yr}$, corresponding to a period of about 227000 years [33].

Through the chaotic dynamics of (2), the fundamental frequencies $\{g_1, s_1\}$ change over time. Mercury’s secular motion might enter into resonance with the external periodic forcing if $g_1$ or $s_1$ comes close to one of the frequencies $g_5$, $g_2$ or $s_2$. In particular, the Mercury-Jupiter perihelion resonance, between $g_1$ and $g_5$, might trigger Mercury’s destabilization [20–23]. The three curves of equations $g_1(I, J) = g_5$, $s_1(I, J) = s_2$ and $g_1(I, J) = g_2$ can be represented in the $(I, J)$ plane, together with the current values of Mercury’s action variables. We obtain in Fig. (2) the so-called “resonance map” which is now widely used for weakly non-integrable systems [28, 29].

The curve of equation $g_1(I, J) = g_2$ cannot be seen in Fig. (2) because this resonance is reached for negative values of action variables, whereas action variables are always positive. We write (2) as $H = \tilde{H} + H_{\text{pert}}$, with

$$\begin{align*}
\tilde{H} &= H_{\text{int}} + E_2 \sqrt{T} \cos(\varphi) + S_2 \sqrt{J} \cos(\psi), \quad (4) \\
H_{\text{pert}} &= E_T \sqrt{T} \cos(\varphi + (g_2 - g_5) t + \beta). \quad (5)
\end{align*}$$

Even if it is of the same amplitude as the two other angular terms, the term $H_{\text{pert}}$ given by (5) creates a weak perturbation for Mercury’s long-term evolution. To find the order of magnitude at which $H_{\text{pert}}$ affects the long-term dynamics of Mercury, we employ Lie transform methods [29] with the special software TRIP [34].

The perturbation $H_{\text{pert}}$ can be integrated, which means that there exists new action-angle variables and a canonical transformation such that Mercury’s Hamiltonian can be put in the form

$$H' = \tilde{H}'(I', J', \varphi', \psi') + H_{\text{pert}}'(I', J', \varphi', \psi', (g_2 - g_5) t), \quad (6)$$

where the order of magnitude of $H_{\text{pert}}'$ is much smaller than $H_{\text{pert}}$. The Lie transform creates periodic terms in $H_{\text{pert}}'$ that contain new combinations of the angles $\varphi$, $\psi$ and $(g_2 - g_5) t$ (given in appendix B1). The difference between $H_{\text{pert}}$ and $H_{\text{pert}}'$ is that the angular terms of the latter are resonant, which means that their frequencies can vanish. The existence of such resonant terms, even of small amplitude, generate long-term chaotic motion.

In the new canonical variables, the Hamiltonian (6) defines a dynamical system with two well separated time scales. Indeed, on a time scale of the order of $\frac{1}{\sqrt{T}}$, the canonical action-angle variables evolve according to Hamilton’s equations of motion. The flow is chaotic with a Lyapunov time $\tau_L$ of the order of one million years [25]. $\tilde{H}'$ evolves through

$$\dot{\tilde{H}}' = \{H_{\text{pert}}', \tilde{H}'\}, \quad (7)$$

sets a new time scale in the dynamical system. In Eq. (7), the notation $\{\}$ represents the canonical Poisson brackets. Eq. (7), shows that $\tilde{H}'$ is a slow variable, because its time evolution is driven by $H_{\text{pert}}' \ll H_{\text{pert}}$. As will become clear in the following, $\tilde{H}'$ remains almost constant on the fast time scale, and has only significant variations on a timescale of a few hundred million years.
FIG. 2: Level curves of $H_{int}(I, J)$ in action space. The surface defined by $H_{int}(I, J)$ has the structure of a saddle. Mercury currently satisfies $H_{int} > H_{cr}$ and is located in the bounded domain. For destabilization to occur, Mercury has to cross the saddle and enter the unbounded domain.

Distribution of the first destabilization times of Mercury: We now discuss qualitatively the implications of the existence of a slow variable for Mercury’s destabilization. This discussion is best understood looking at the level curves of $H_{int}(I, J)$ in action space displayed in Fig. (2). It can be seen that the landscape defined by $H_{int}(I, J)$ has the topology of a saddle. The saddle is exactly located at the intersection between the two resonances $g_1 - g_5$ and $s_1 - s_5$, with the value $H_{int} = H_{cr}$. The domain of equation $H_{int}(I, J) > H_{cr}$ has two disjoint components, one bounded (bottom left) and the other unbounded (top right), only connected by the saddle point $(I_{cr}, J_{cr})$. The initial orbital parameters of Mercury $e$ and $i$ are located in the bounded domain, which means that the orbit is stable. When $H_{int}$ reaches the value $H_{cr}$, Mercury can cross the saddle and enter the unbounded domain of phase space. This latter event defines the destabilization of its orbit.

We explain in appendix B3 how the above simple criterion for Mercury’s destabilization translates into an equivalent criterion for $H'$: there exists a threshold $h_{cr}$ for which the first destabilization time for Mercury’s orbit exactly corresponds to the first hitting time of $H'$ to $h_{cr}$.

The full expression of $H'$ is an intricate serie composed of a large number of periodic terms of small amplitude, the explicit expression of which is difficult to handle. Following the route of [25], we prefer to use in practice the local time average $h(t) = \langle \hat{H} \rangle_{[t-\theta, t]}$ as an approximation of $H'$, which is much simpler to implement numerically. The time frame $\theta$ has to be much larger than the frequency of the fast variations of $\hat{H}$ given by the frequency $g_2 - g_5$, according to Eq. (5). We choose $\theta \gg \frac{1}{g_2 - g_5}$. As an example, the time variations of $\hat{H}(t)$ compared to those of $h(t)$ is displayed in Fig. (3) with $\theta = 2 \text{ Myr}$. We then identify the diffusion Eq. (8) for $H'$ and that for $h$.

Tracking numerically the value of $h(t)$ of trajectories leading to destabilization confirms that the distribution $h(\tau)$ (where $\tau$ is the destabilization time) is peaked at the value $h_{cr} = -0.048$, which can thus be identified as the destabilization threshold. In addition to the lower bound $h_{cr}$, we must add a reflective boundary for a upper value $h_{sup}$, which accounts for the fact that the chaotic region

FIG. 3: A trajectory $\hat{H}(t)$ (cyan) compared to its local time average $h(t)$ (blue). The local time averaging of $\hat{H}(t)$ suppresses the fast oscillations that do not correspond to long-term variations. For the long-term chaotic dynamics, $h(t)$ is an slow variable that follows a standard Brownian motion.

Diffusion of the slow variable: The theory of white noise limit for slow-fast dynamical systems (see e.g. [30]) suggests that on a timescale much larger than $\tau_L$, the dynamics (7) is equivalent to a diffusion process. This limit is valid within the reasonable assumption that the variations of $\hat{H}'$ on the timescale $\tau_L$ are sufficiently small. Two additional phenomenological approximations can be made: first, numerical simulations performed with the dynamics (7) show that the drift is very small compared to the diffusion coefficient, and can be neglected. Second, the range of $\hat{H}'$ values before destabilization is small, and the diffusion coefficient can be considered as constant. The long-term evolution of the slow variable $\hat{H}'$ can thus be modeled by the standard Brownian motion

$$\dot{\hat{H}}' = D \xi(t),$$

where $\xi(t)$ is the Gaussian white noise process with correlation function $\langle \xi(t)\xi(t') \rangle = \delta(t - t')$. Unfortunately, the exact expression for $D$ involves the full correlation function of the Hamiltonian flow defined by $H'$. It is too intricate to be useful in practice. Starting from the formal expression, it is shown in appendix B2 that a reasonable order of magnitude is

$$D \approx 2 |H_{pert}|^6 \tau_L/|\hat{H}'|^4,$$

where $|\hat{H}'|$ and $|H_{pert}|$ are orders of magnitude of (5) and (4) respectively. Eq. (9) is our first important theoretical result. Evaluating Eq. (9) gives $D \approx 7.2 \times 10^{-7} \text{ Myr}^{-3}$. The order of magnitude of the associated diffusion time scale for $\hat{H}'$ is evaluated to one billion years. Those results justifies the self-consistently of the choice for the slow variable.

Distribution of the first destabilization times of Mercury: We now discuss qualitatively the implications of the existence of a slow variable for Mercury’s destabilization. This discussion is best understood looking at the level
of phase space before destabilization is bounded. Destabilization of Mercury occurs when the standard Brownian motion defined by \( h(t) \) reaches the critical value \( h_{cr} \).

The mechanism is illustrated in Fig. (4). For a standard Brownian motion of diffusion coefficient \( D \), the distribution \( P(\tau) \) of first hitting times of the value \( h_{cr} \) can be derived exactly (see appendix C). The latter is displayed in Fig. (4), together with the distribution obtained from direct numerical simulations of Hamilton’s equations. The diffusion coefficient \( D \) is the only fitting parameter in the reduced model of the inner Solar System with deterministic chaos, we have shown that the first exit time \( \tau \) for a Mercury-Jupiter resonance can be computed from the standard Brownian motion describ- ing the dynamics of the instanton, see appendix D).

Using this numerical value, Fig. (4) shows that the diffusive model Eq. (8) gives a very good qualitative agreement with the direct numerical simulations. The fitted value of \( D \) is also in agreement with Eq. (9) and its order of magnitude \( D \approx 7.2 \times 10^{-7} \text{ Myr}^{-3} \).

**Instanton paths for Mercury:** We now focus on the probability that Mercury’s orbit is destabilized in short times \( \tau_L \ll \tau \ll \tau^* \), where \( \tau^* \) is the maximum of \( \rho(\tau) \). Consider the probability \( P(\tau) = \int_{\tau}^{\infty} \rho(\tau')d\tau' \) that the destabilization of Mercury’s orbit occurs in a time shorter than \( \tau \). Table (I) gives some orders of magnitude of \( P(\tau) \). The leading behavior of \( \rho(\tau) \) at short times is dominated by the exponential term \( \rho(\tau) \approx e^{-\frac{\tau^2}{4D}} \), where \( \tau^* \approx 1.56 \times 10^9 \) years.

The exponential growth is the signature that short-term destabilizations of Mercury are rare events. The slow variable \( h(t) \), conditioned on the fact that destabilization occurs at a given time \( \tau \), is predictable by the instanton path. The standard Brownian motion describing the dynamics of \( h(t) \) is simple enough such that the instanton path can be computed exactly: it is the straight path starting at \( h(0) \) and reaching \( h_{cr} \) at time \( \tau \). In the present case, we can even obtain a more precise result, namely the exact expressions for the average and the variance of all trajectories destabilized in a given time \( \tau \). The theoretical and numerical results for a particular destabilization time \( \tau = 445 \) million years is displayed in Fig. (5). The middle blue curve displays the averaged trajectory obtained through direct numerical averaging of all trajectories leading to destabilization at time \( \tau \). In addition, the upper and lower blue curves display the variance of this ensemble of trajectories, and thus show how the trajectories depart from the most probable trajectory. We have superimposed three red curves that represent the average and variance of the probability distribution \( P[h, t|(h_{cr}, h, \tau), (h_0, 0)] \) to observe the value \( h \) at time \( t \), with the constrain \( h(\tau) = h_{cr} \), for the standard Brownian motion \( h(t) \).

The agreement between the diffusive model of \( h \) and Mercury’s dynamics can be considered as excellent, notwithstanding the small discrepancy at short times coming from the finite correlation time of Mercury’s secular dynamics. This is a second confirmation that the diffusive model for the slow variable is consistent both for the prediction of Mercury’s first destabilization time distribution, and for the prediction of instantons.

Within the Batygin–Morbidelli–Holman dynamics, a reduced model of the inner Solar System with deterministic chaos, we have shown that the first exit time for a Mercury–Jupiter resonance can be computed from an effective stochastic diffusion. We predicted the related instanton and demonstrated that path probabilities actually concentrate close to this instanton, for events
which occur within a few hundred million years. While the Batygin–Morbidelli–Holman contains some of the features of the inner Solar System dynamics, it neglects others. Clearly, this model should not be expected to quantitatively predict first exit times for the actual Solar System. Nevertheless, these striking results suggest that the destabilization of the Solar System might indeed occur though an instanton phenomenology. Our work open this question, which should be addressed within other models, that have to be realistic enough for describing faithfully the actual dynamical mechanisms, but simple enough for a proper statistical study.

Acknowledgments: We are highly indebted to F. Mogavero and J. Laskar for their constant help all along this work and in particular for having shared with us the private version of TRIP and the quasiperiodic decomposition of planetary motion. We also thank C. Batygin and A. Morbidelli for having shared their previous results with us, and for interesting discussions. The research leading to these results has received funding from the European Research Council under the European Union’s seventh Framework Program (FP7/2007-2013 Grant Agreement No. 616811).

[33] This value is actually specific of our model. The current value of $g_1$ for the real Solar System would be about $5.60^\circ/yr$.

[34] TRIP is a general computer algebra system dedicated to celestial mechanics developed at the IMCCE (Copyright 1988-2019, J. Laskar ASD/IMCCE/CNRS). TRIP is particularly efficient to handle series with a large number of terms like those usually appearing in Lie transforms.

**Appendix A: Coefficients of Mercury’s Hamiltonian**

Mercury’s simplified Hamiltonian is given by Eq. (2) in the main text

$$H = H_{int}(I,J) + E_2 \sqrt{I} \cos(\varphi) + S_2 \sqrt{J} \cos(\psi) + E_T \sqrt{I} \cos(\varphi + (g_2 - g_5) t + \beta),$$

(A1)

with

$$H_{int}(I,J) = (E_1 + g_5) I + E_3 I^2 + (S_1 + s_2) J + S_3 J^2 + F_{ES} I J.$$ (A2)

We give in table (II) the numerical value for the coefficients.

**Appendix B: Diffusion process for the slow variable**

The present section is quite technical. We derive the formal expression of the diffusion coefficient $D$ in Eq. (8) using Lie transform methods, and we explain how a good order of magnitude for $D$ can be deduced from the result. The computation have been done with the software TRIP developed at the IMCCE by Jacques Laskar and Mickael Gastineau (https://www.imcce.fr/trip/), which is precisely devoted to the computation of series in celestial mechanics.

1. **List of third order resonances amplitudes**

We start from the Hamiltonian (A1) (Eq. (2) of the main text), that we decompose in two parts

$$H = \tilde{H}(I,J,\varphi,\psi) + eH_{pert}(I,J,\varphi,\psi,gt),$$

(B1)

where $g = g_2 - g_5$, with $\tilde{H}$ and $H_{pert}$ given by Eqs. (4-5) of the main text

$$\tilde{H} = H_{int}(I,J) + E_2 \sqrt{I} \cos(\varphi) + S_2 \sqrt{J} \cos(\psi).$$ (B2)
FIG. 6: The resonance map in action space. The blue lines represent the first order resonances, the red lines to the second order resonances, and the green lines to third order. Mercury’s current position is close to an intersection of many third order resonances.

\[ H_{\text{pert}} = E_T \sqrt{I} \cos (\varphi + (g_2 - g_5) t + \beta). \]

The parameter \( \epsilon \) in Eq. (B1) is used below to define a hierarchy of Lie transforms, but is set to one at the end of the calculation. Table (II) gives the values to compute the order of magnitude of \( |\tilde{H}| \) and \( |H_{\text{pert}}| \) respectively.

We find \( |\tilde{H}| \approx 3 \times 10^{-2} \text{ arcsec/yr}, \) and \( |H_{\text{pert}}| \approx 9 \times 10^{-3} \text{ arcsec/yr}. \) We perform a canonical change of variables \( \{I, J, \varphi, \psi\} \to \{I', J', \varphi', \psi'\} \) with Lie transform methods to integrate the term \( H_{\text{pert}} \) and all non-resonant harmonics. The procedure is described with all details in many references [29, 31], but we explain briefly below the general principle.

The canonical transformation is given by a function \( \chi(I, J, \varphi, \psi) \) such that the new Hamiltonian \( H' \) can be computed by

\[ H' = e^{\chi} H, \]

\[ = H + \{\chi, H\} + \frac{1}{2} \{\chi, \{\chi, H\}\} + \ldots \]

where the symbol \( \{\} \) represents the canonical Poisson brackets. The aim is then to choose carefully \( \chi \) to eliminate all non-resonant terms in \( H' \). This can be achieved order by order in \( \epsilon \). We expand the function \( \chi \) in power of \( \epsilon \) as

\[ \chi = \epsilon \chi_1 + \epsilon^2 \chi_2 + \ldots \]

and we solve order by order in \( \epsilon \) the homologic equation for \( \chi_n \)

\[ \{\chi_n, H_{\text{int}}\} + R_n = 0, \]

where \( H_{\text{int}} \) is given by Eq. (A2) and \( R_n \) gathers all non-resonant terms of order \( \epsilon^n \) that are created by the Lie transforms up to order \( n - 1 \). The procedure leads to the so-called resonant normal form. The Hamiltonian in resonant normal form only contains terms that can not be integrated out because they are resonant in the accessible domain of phase space. The resonant combination of angles up to third order are displayed in Fig (6).

The computations of the Lie transforms up to order 3 in \( \epsilon \) can be done with the special software TRIP. At each order in \( \epsilon \) in the Lie transforms, we keep all terms that involve a resonant angle in the accessible domain of phase space.
space. The algorithm gives the Hamiltonian \((A1)\) in terms of the new canonical variables

\[
H' (I', J', \varphi', \psi', t) = \tilde{H}' (I', J', \varphi', \psi') + \varepsilon^3 H'_{\text{pert}} (I', J', \varphi', \psi', gt) + O(\varepsilon^4),
\]

(\text{B3})

where \(\tilde{H}'\) is the autonomous part of the Hamiltonian, and \(H'_{\text{pert}}\) is the part of the Hamiltonian with all resonant angles of second and third order. The part \(H'_{\text{pert}}\) has the form

\[
H'_{\text{pert}} (I', J', \varphi', \psi', gt) = F_{(2,0,1)} (I', J') \cos (2\varphi' + gt)
+ F_{(2,1,1)} (I', J') \cos (2\varphi' + \psi' + gt)
+ F_{(1,2,1)} (I', J') \cos (\varphi' + 2\psi' + gt).
\]

(\text{B4})

We have explicitly computed the coefficients \(F_{(2,0,1)}, F_{(2,1,1)}, F_{(1,2,1)}\) with TRIP, their explicit expression, together with the expression of \(\tilde{H}'\) are available on request to the authors.

2. Explicit expression for \(D\)

In the present section, we apply stochastic averaging to the dynamics

\[
\hat{\tilde{H}}' = \left\{H, \tilde{H}'\right\}
= \varepsilon^3 \left\{H'_{\text{pert}}, \tilde{H}'\right\}.
\]

(\text{B5})

to find an order of magnitude for the diffusion of \(\tilde{H}'\). To simplify the computations and get an explicit expression for the diffusion coefficient, we have chosen reasonable assumptions.

We first notice that the terms of largest amplitude in \(\tilde{H}'\) are the terms that depend only on the action variables. To leading order, the expression of \(\tilde{H}'\) reduces to

\[
\tilde{H}' (I', J', \varphi', \psi') \approx H_{\text{int}} (I', J'),
\]

with the expression of \(H_{\text{int}}\) given by Eq. (A2).

Using the above approximation in the right-hand side of (\text{B5}), the dynamics of \(\tilde{H}'\) reduces to

\[
\dot{\tilde{H}}' = -\varepsilon^3 \frac{\partial H_{\text{int}}}{\partial I'} \frac{\partial H'_{\text{pert}}}{\partial \varphi'} - \varepsilon^3 \frac{\partial H_{\text{int}}}{\partial J'} \frac{\partial H'_{\text{pert}}}{\partial \psi'}.
\]

(\text{B6})

With the expression (\text{B4}), Eq. (\text{B6}) can be rewritten as

\[
\dot{\tilde{H}}' (I', J', \varphi', \psi', gt) = \mathcal{F}_{(2,0,1)} (I', J') \sin (2\varphi' + gt)
+ \mathcal{F}_{(2,1,1)} (I', J') \sin (2\varphi' + \psi' + gt)
+ \mathcal{F}_{(1,2,1)} (I', J') \sin (\varphi' + 2\psi' + gt),
\]

(\text{B7})

where \(\{\mathcal{F}_{(2,0,1)}, \mathcal{F}_{(2,1,1)}, \mathcal{F}_{(1,2,1)}\}\) are new coefficients obtained from the expression of \(\{F_{(2,0,1)}, F_{(2,1,1)}, F_{(1,2,1)}\}\).

Using stochastic averaging for Eq. (\text{B7}) (see e.g. [30]), the long-term evolution of \(\tilde{H}'\) is equivalent in law to a diffusion process

\[
\tilde{H}' = a \left(\tilde{H}'\right) + \sqrt{D \left(\tilde{H}'\right)} \xi (t).
\]

(\text{B8})

The drift term \(a \left(\tilde{H}'\right)\) comes from averaging Eq. (\text{B7}) over fast motion, and from the correlations between fast and slow motion. Numerical simulations done with the dynamics (\text{B7}) show that the drift is very small compared to the diffusion, and can be neglected, at least in the range of timescale of one billion years we are interested in. In the following, we focus on the diffusion coefficient \(D \left(\tilde{H}'\right)\).

The diffusion coefficient can be expressed with a Green-Kubo formula involving the correlation function of the right-hand side of Eq. (\text{B7}). The complete expression is quite long. In this section, in order to get reasonable orders of
magnitude, we assume that the cross correlations between different resonant angles give no appreciable contributions. For example, we neglect correlations such as

$$\langle F_{(2,0,1)}(I'(t), J'(t)) \sin(2\varphi'(t) + gt) \rangle_{\bar{H}}.$$ 

The functions $F(I'(t), J'(t))$ in Eq. (B7) can be decomposed between an non-zero averaged part, and a small perturbation with zero average. Clearly, the leading order can be computed retaining only the averaged component of $F$. We thus do not longer take into account the dependance on action variables in (B7) and we systematically replace the functions $F(I'(t), J'(t))$ by a constant corresponding to their order of magnitude. With the approximations discussed above, the order of magnitude for $D(\bar{H}')$ is

$$D(\bar{H}') \approx 2 |F_{(2,0,1)}|^2 \int_0^{+\infty} dt \langle \sin(2\varphi(t) + gt) \rangle_{\bar{H}}.$$ 

In Eq. (B9), the notation $\langle \cdot \rangle_{\bar{H}}$ means that the average should be done with a fixed value $\bar{H}'$.

A last approximation is done to compute the correlation functions of the sinus terms inside the integrals. The two angles $2\varphi + \psi + gt$ and $\varphi + 2\psi + gt$ correspond to the resonances $2q_1 - g_0 - g_2 + \frac{s_1 - s_2}{2}$ and $g_1 - g_2 + 2(s_1 - s_2)$ respectively, and are resonant right at the center of the accessible domain as displayed in Fig. 6. Their average frequency is close to zero. On the contrary, the angle $2\varphi + gt$ is only resonant at the domain boundaries. We choose to keep only the contribution from the last two terms in the right-hand side of Eq. (B9). Let $\tau_L$ be the correlation time of the angle variables, we choose the approximation

$$2\varphi(t) + \psi(t) + gt \approx \varphi(t) + 2\psi(t) + gt \approx \theta + W\left(\frac{t}{\tau_L}\right),$$

where $W(t)$ is the standard Brownian motion and $\theta$ is a random variable with uniform probability distribution over $[0, 2\pi]$. The term $W\left(\frac{t}{\tau_L}\right)$ accounts for the fact that a resonant angle crosses the resonant conditions and switches its frequency within a time $\approx \tau_L$. We mention that the relation between the Lyapunov exponent of a chaotic Hamiltonian dynamics with one degree of freedom and two resonances has been precisely studied by [32], but the situation with two degrees of freedom is more subtle and the results cannot be directly applied here. The expression (B9) for the diffusion coefficient becomes

$$D \approx 2 \left(|F_{(2,1,1)}|^2 + |F_{(1,2,1)}|^2\right) \int_0^{+\infty} dt \langle \sin(\theta + W\left(\frac{t}{\tau_L}\right)) \rangle \sin(\theta).$$ (B10)

The computation of the integral in (B10) is straightforward. The final result is

$$D \approx 2 \left(|F_{(2,1,1)}|^2 + |F_{(1,2,1)}|^2\right) \tau_L.$$ (B11)

Finally, we have used the numerical value of the Lyapunov time $\tau_L \approx 1.1$ Myr obtained with numerical simulations, and we have evaluated numerically the explicit expressions of $F_{(2,1,1)}$ and $F_{(1,2,1)}$. We get the order of magnitude

$$D \approx 1.15 \times 10^{-5} M yr^{-3}.$$ (B12)

We further show that the order of magnitude (B12) can be obtained in a much more heuristic manner. We have proven that diffusion of the slow variable $\bar{H}'$ is due to third order secular resonances, that come to order $e^3$ in the Hamiltonian (B3). The order of magnitude for $F_{(2,1,1)}$ and $F_{(1,2,1)}$ roughly corresponds to $\frac{H_{pert}^3}{|\bar{H}|^2} \times |\bar{H}|^2$ and expression (B11) can be written

$$D \approx 2 \frac{|H_{pert}|^6}{|\bar{H}|^2} \tau_L.$$ (B13)
where $|\tilde{H}|$ is the order of magnitude of the averaged BMH Hamiltonian. Expression (B13) corresponds to Eq. (9) of the main text, and direct evaluation with $|\tilde{H}| = 3.10^{-2}$ arcsec/yr, $|H_{\text{pert}}| \approx 9 \times 10^{-3}$ arcsec/yr, and $\tau_L \approx 1.1 \text{ Myr}$ gives

$$D \approx 7.2 \ast 10^{-7} \text{ Myr}^{-3}.$$  

3. Destabilization criterion for Mercury’s orbit

We explain in the present section how the stability of Mercury’s orbit can be directly related to the value of the slow variable $\tilde{H}'$. $\tilde{H}'$ is obtained by Lie transforms of $\tilde{H}$ given by (B2). The explicit expression of $\tilde{H}'$ is thus composed of a part that depends only on action variables, and a large number of periodic terms that involve the angle variables. The leading terms in the action-dependent part of $\tilde{H}'$ is given by $H_{\text{int}}$. We can thus crudely write the decomposition

$$\tilde{H}'(I,J,\varphi,\psi,t) = H_{\text{int}}(I,J) + G(I,J,\varphi,\psi,t),$$

where $G$ is some intricate function. For any fixed value of $\tilde{H}'$, the variations of $H_{\text{int}}$ are bounded between an upper and a lower value

$$\Gamma_{\text{inf}}(\tilde{H}') \leq H_{\text{int}} \leq \Gamma_{\text{sup}}(\tilde{H}')$$

that depend in a non-trivial way of the maximal amplitude of $G(I,J,\varphi,\psi,t)$. The destabilization criterion $H_{\text{int}} = H_{cr}$ thus translates into the equivalent criterion

$$\Gamma_{\text{inf}}(\tilde{H}') = H_{cr}.$$ 

Let us call $h_{cr}$ the value such that $\Gamma_{\text{inf}}(h_{cr}) = H_{cr}$, Mercury’s destabilization is directly related to the event $\tilde{H}' = h_{cr}$. This argument shows why destabilization of Mercury is directly related to the event $\tilde{H}'$ hitting the threshold value $h_{cr}$.

Given the complexity of the explicit expressions of $\tilde{H}'$ and $\Gamma_{\text{inf}}(\tilde{H}')$, the destabilization criterion has to be treated in an empirical manner. The value of $\tilde{H}'$ is better replaced by the local time average $h(t) = \langle \tilde{H} \rangle_{[t-\theta,t+\theta]}$ where the time frame of length $\theta$ should satisfy $\theta \gg \frac{1}{2\pi \cdot g_s}$. This approximation is described precisely in the main text. in practice, we have chosen $\theta = 2$ Myr. To compute the threshold value $h_{cr}$, we also use a numerical approach: we record the values of $h(t_{cr})$ at the destabilization time, for a large number of destabilized trajectories. The distribution of $h(t_{cr})$ is peaked at a particular value, thus confirming the existence of the threshold $h_{cr}$. We find $h_{cr} \approx -0.048$ arcsec/yr.

Appendix C: Explicit expression for the distribution of first exit times of a Brownian motion from a bounded domain

In the present section, we show how to derive the probability distribution function $\rho(\tau)$ of first exit time of a standard Brownian motion from the domain $[h_{cr}, h_{sup}]$, starting at $h_0$ and with reflective condition at $h = h_{sup}$.

Let $G(h,t) := \int_{h_{cr}}^{h_{sup}} \mathbb{P}(h',t|h,0) \, dh'$ be the probability that the Brownian particle starting at $h$ is still in the domain $[h_{cr}, h_{sup}]$ at time $t$. It can be shown that the distribution $G(h,t)$ satisfies the same diffusion equation as $\mathbb{P}(h',t|h,0)$ (see [30])

$$\frac{\partial G}{\partial t} = D \frac{\partial^2 G}{\partial h^2}. \quad (C1)$$

At time $t = 0$, the particle is inside the domain, which means that $G(h,0) = 1$ for all $h \in [h_{cr}, h_{sup}]$. The absorbing boundary condition at $h = h_{cr}$ and the reflecting boundary condition at $h = h_{sup}$ can be equivalently expressed with the distribution $G$ as

$$\text{for all } t > 0, \quad \left\{ \begin{array}{l} G(h_{cr},t) = 0, \\
\frac{\partial G}{\partial h}(h_{sup},t) = 0. \end{array} \right. \quad (C2)$$
We solve the problem (C1-C2) by decomposing the solution into proper modes. Let us introduce the standard scalar product
\[ \langle f, g \rangle = \frac{2}{h_{sup} - h_{cr}} \int_{h_{cr}}^{h_{sup}} f(h)g(h)dx. \]

It can be checked that the family of functions
\[ e_n(h) = \cos \left( \pi \left( n + \frac{1}{2} \right) \frac{h - h_{sup}}{h_{cr} - h_{sup}} \right) \text{ with } n \in \mathbb{N} \]
form an orthonormal basis of all functions \( G(x,t) \) satisfying the boundary conditions (C2). The solution of (C1-C2) can thus be expressed as the Fourier series
\[ G(h,t) = \sum_{n=0}^{\infty} g_n(t)e_n(h), \quad (C3) \]
where the coefficients \( g_n(t) \) are defined as the projection of \( G \) on the orthonormal basis, that is \( g_n(t) := \langle G(h,t)e_n(h) \rangle \).

Using the Fourier decomposition (C3), we find that
\[ g_n(t) = g_n(0)e^{-\pi^2(n+\frac{1}{2})^2 \frac{D}{(h_{sup} - h_{cr})^2} t}. \]
The value \( g_n(0) \) can be found with the initial condition \( G(h,0) = 1 \). We get
\[ g_n(0) = \langle G(h,0)e_n(h) \rangle = \frac{2}{\pi} \frac{(-1)^n}{n + \frac{1}{2}}. \]

Finally, the solution \( G(h,t) \) can be expressed explicitly as
\[ G(h,t) = 2 \frac{h - h_{cr}}{h_{cr} - h_{sup}} \sum_{n=0}^{\infty} \frac{(-1)^n}{n + \frac{1}{2}} \cos \left( \pi \left( n + \frac{1}{2} \right) \frac{h - h_{sup}}{h_{cr} - h_{sup}} \right) e^{-\pi^2(n+\frac{1}{2})^2 \frac{D}{(h_{sup} - h_{cr})^2} t}. \]

As \( G(h,t) \) is the probability to be still in the domain \([h_{cr}, h_{sup}]\) at time \( t \), it is related to \( \rho(\tau) \) by
\[ G(h,t) = \int_t^{t^+\infty} \rho(\tau)d\tau. \]

Therefore, the time derivative of Eq. (C4) gives the explicit expression of \( \rho(\tau) \)
\[ \rho(\tau) = \frac{2\pi D}{(h_{sup} - h_{cr})^2} \sum_{n=0}^{\infty} \frac{(-1)^n}{n + \frac{1}{2}} \cos \left( \pi \left( n + \frac{1}{2} \right) \frac{h_0 - h_{cr}}{h_{sup} - h_{cr}} \right) \exp \left( -\pi^2 \left( n + \frac{1}{2} \right)^2 \frac{D\tau}{(h_{sup} - h_{cr})^2} \right). \]

This expression is used for the fit in Fig. (4) of the main text.

**Appendix D: Average and variance of a Brownian bridge**

In the present section, we show how to obtain explicitly the red curves in Fig. (5) of the main text.

The aim is to compute the probability
\[ \rho^{\tau_{ex}}(h,t) := P(h,t|\{h_0,0\} \cap \{\tau = \tau_{ex}\}) \quad (D1) \]
to have a trajectory at location \( h \) at time \( t \) with the constrains that the trajectory starts at \( h_0 \) and exits the domain at time \( \tau = \tau_{ex} \), for a standard Brownian motion of diffusion coefficient \( D \). The inequality \( 0 < t < \tau_{ex} \) should be satisfied. Using Bayes theorem and Markov property, the probability distribution (D1) can be written as
\[ \rho^{\tau_{ex}}(h,t) = \frac{P(\tau = \tau_{ex}|h,t)P(h,t|h_0,0)}{P(\tau = \tau_{ex}|h_0,0)}. \quad (D2) \]
All probability distributions in the right-hand side of (D2) have explicit expressions. The probability $\mathbb{P}(\tau = \tau_{ex}|h,t)$ to exit the domain starting at a given position can be obtained from equation (C5) in the limit $\tau_{sup} \to +\infty$. We have thus

$$\mathbb{P}(\tau = \tau_{ex}|h,t) = \frac{1}{\tau_{ex} - t} \frac{h - h_{cr}}{4\pi \tau_{ex} t} e^{-\frac{(h-h_{cr})^2}{4\tau_{ex}t}},$$

$$\mathbb{P}(\tau = \tau_{ex}|h_0,0) = \frac{1}{\tau_{ex}} \frac{h_0 - h_{cr}}{4\pi \tau_{ex} \tau_{ex}} e^{-\frac{(h_0-h_{cr})^2}{4\tau_{ex}^2}}.$$

The last term $\mathbb{P}(h,t|h_0,0)$ is simply the solution of the free diffusion equation in an infinite domain, which is the classical result

$$\mathbb{P}(h,t|h_0,0) = \frac{1}{4\pi \tau_{ex} t} e^{-\frac{(h-h_0)^2}{4\tau_{ex}t}}.$$

After some algebra, we obtain the following explicit expression for $\rho^{\tau_{ex}}(h,t)$ (valid for $h > h_{cr}$ and $0 < t < \tau_{ex}$)

$$\rho^{\tau_{ex}}(h,t) = \frac{h - h_{cr}}{h_0 - h_{cr}} \left( \frac{\tau_{ex}}{\tau_{ex} - t} \right)^{3/2} \frac{1}{4\pi \tau_{ex} t} \left( \frac{1}{4\tau_{ex} s(1-s)} \right)^2 \exp \left( -\frac{(h-h_{cr} + (1-s) (h_0 - h_{cr}))^2}{4\tau_{ex} s(1-s)} \right),$$

(D3)

where we have introduced the ratio $s = \frac{t}{\tau_{ex}}$. It can be quite easily checked that $\int_{0}^{\tau_{ex}} \rho^{\tau_{ex}}(h,t)dh = 1$, because $\rho^{\tau_{ex}}(h,t)$ is a probability density.

The instanton trajectory, and the variance of the distribution around the instanton can be obtained with the first and the second moments of the distribution (D3). We define the average trajectory $\{\bar{h}(t)\}_{0\leq t<\tau_{ex}}$ as

$$\bar{h}(t) = \int_{h_{cr}}^{+\infty} h \rho^{\tau_{ex}}(h,t)dh.$$  

(D4)

There is a small difference between the average trajectory defined by (D4) and the instanton trajectory $\tilde{h}(t)$ which is the trajectory of highest probability. The trajectory of highest probability is the straight trajectory of equation

$$\tilde{h}(t) = \frac{t}{\tau_{ex}} h_{cr} + \left( \frac{\tau_{ex} - t}{\tau_{ex}} \right) h_0.$$  

The distribution of trajectories that exit the domain for short times is more and more concentrated around the trajectory of highest probability when $\tau_{ex}$ goes to zero. To first approximation, $\bar{h} \approx \tilde{h}$ when $\tau_{ex}$ is small compared to $\tau^*$. However, the average trajectory is a bit curved when $t$ gets closer to $\tau_{ex}$ because of the influence of the absorbing boundary condition. We represent in Fig. (5) of the main text the averaged trajectory instead of the instanton trajectory because it can more easily be compared to numerical results. To study the trajectories dispersion around the instanton, we can also compute the standard deviation

$$\delta \tilde{h}(t) = \left[ \int_{h_{cr}}^{+\infty} (\bar{h}(t) - \tilde{h}(t))^2 \rho^{\tau_{ex}}(h,t)dh \right]^{1/2}.$$  

(D5)

Expressions (D4) and (D5) can be evaluated numerically. The three red curves in Fig. (5) of the main text are those of equations (from highest to lowest) $h(t) = h(t) + \delta \tilde{h}(t)$, $h(t) = \tilde{h}(t)$ and $h(t) = h(t) - \delta \tilde{h}(t)$ respectively, for $\tau_{ex} = 445$ million years.
