Abstract

Stress can facilitate disease processes and causes strain on the health care budgets. It is responsible or involved in many human ailments of our time, such as cardiovascular illnesses, particularly related to the psychosocial stressors of daily life, including work. Besides pharmacological or clinical medical treatment options, behavioral stress reduction is much-needed. These latter approaches rely on an endogenous healing potential via life-style modification. Hence, research has suggested different ways and approaches to self-treat stress or buffer against stressors and their impacts. These self-care-centred approaches are sometimes referred to as mind-body medicine or multi-factorial stress management strategies. They consist of various cognitive behavioral techniques, as well as relaxation exercises and nutritional counselling. However, a critical and consistent element of modern effective stress reduction strategies are exercise practices. With regard to underlying neurobiological mechanisms of stress relief, reward and motivation circuitries that are imbedded in the limbic regions of the brain are responsible for the autoregulatory and endogenous processing of stress. Exercise techniques clearly have an impact upon these systems. Thereby, physical activities have a potential to increase mood, i.e., decrease psychological distress by pleasure induction. For doing so, neurobiological signalling molecules such as endogenous morphine and coupled nitric oxide pathways get activated and finely tuned. Evolutionarily, the various activities and autoregulatory pathways are linked together, which can also be demonstrated by the fact that dopamine is endogenously converted into morphine which itself leads to enhanced nitric oxide release by activation of constitutive nitric oxide synthase enzymes. These molecules and mechanisms are clearly stress-reducing.

Key words: nitric oxide, morphine, dopamine, pleasure, motivation, neurobiology, autoregulation, health, running, mind-body medicine.

Introduction

Stress is an eminent challenge nowadays. This seems to be especially true for modern service-oriented societies, where the stress phenomenon and its impact on individual health, work force, environments, as well as the national economies and business profits, even overall “happiness scores” (i.e., the well-being of individuals and the society on a larger scale), is evident [1-6]. In fact, not only seems stress to be increasing in reference to medical operating figures and determinants, but has particularly
penetrated into the daily lives of even the young and otherwise healthy, thus causing potential threat [1-3]. In the course of this increasing stress proliferation and overflow, as it seems, the remaining “islands of stillness” and daily life recoveries seem to advance backward, and people search for wellness and recreation at all kinds of places, e.g., short-time or “wellness in a rush” [4-6].

One of the major problems related to the given description of stress and its significance in our times is that most of the stress that we encounter or perceive seems not to be an actual physical or external life threat, but instead, to some extent, “self-made”, that is, produced in our heads and thoughts, i.e., cognitively, or posed to each other by psychosocial or chronic conflict [1, 4]. Thus, data for the work environments, for example, demonstrate that the psychosocial stress is generally increasing, leading to accelerating absenteeism and/or “presentism” rates (i.e., going to work but not utilizing the full individual potential), all together “unhealthy” for the individuals, the companies, and the societies [1, 3].

No doubt, circumstances and external forces, e.g., financial or economical crisis, are responsible for a lot of threat and stress that people have to face, accessory to demographic or socioeconomic factors, noise, pollution, etc., however, individual behavior and resources are of importance for stress as well, as for stress resilience and relief [4-6]. Thus, besides influencing external and political or environmental factors, which is a predominant and important task for health care, economical and particularly educational policies, the endogenous or self-regulatory potentials to individually reduce or buffer against stress, when stress is simply there (and it is!) or yet has to be faced, is also of significance and should not be neglected.

We have an endogenous and salutogenic potential for stress resilience [5], and to increase or use this potential, it is sometimes helpful to seek professional advice and support, since for many individuals the autoregulation of stress has gotten out of the focus during their life spans and routines, that is, trapped or blocked [4, 6]. Hence, modern stress management approaches help to activate this potential and re-connect to it, and exercise is one of their key elements. Recent neurobiological research explains some of the observations and scientific background.

**Stress**

Stress describes the effects of psychosocial and environmental factors on physical or mental well-being [6, 7]. Stressors and related stress-reactions are often distinguished [4, 6]. Further, stress implies a challenge (stimulus) that requires behavioral, psychological, and physiological changes (adaptations) to be successfully met, therefore using a state of hyperarousal for the initiation of necessary counteracting reactions [6, 7]. This state of hyperarousal involves physiological mechanisms that are known as the stress/emergency response or fight-or-flight response, a set of physiological changes that occur in stressful situations and that prepare the stressed organism either to fight or to flee. The state of alertness had first been described by Walter Cannon – almost 100 years ago [8, 9].

Stress has an impact upon the immune, circulatory, and nervous systems [6]. Therefore, stress may affect immunological [10], cardiovascular [11], and neurodegenerative diseases/mental disorders [12], and this may include both positive and negative aspects [6, 10-12]. Thus, stress can either exert ameliorating or deleterious effects, depending on a multitude of factors (e.g., individual, endogenous, or exogenous elements) [4, 6]. However, clinically, and with reference to modern medical settings, negative influences of stress upon health and disease processes seem to dominate [2, 3, 6, 10-12]. This may especially be true in the ‘Western World’, where stress-related health issues almost seem to have an increasingly epidemic character [1-7].

Additionally, the concept of ‘allostasis’ has been introduced into the field of stress medicine/research by Sterling and Eyer [13], refined by McEwen [14]. Thereby, allostasis, literally meaning “maintaining stability (or ‘homeostasis’) through change” [10, 13, 14], describes the capacity to adapt or to constantly change, i.e., modify, physiological parameters in order to adjust to ever shifting environmental conditions [4, 6, 7, 12]. Hence, we can also speak alternatively about maintaining a ‘state of dynamic balance’ [10-12]. Moreover, ‘allostatic load’ refers to the wear and tear that the body experiences due to repeated cycles of allostasis, i.e., allostatic stress responses, as well as the inefficient turning-on or shutting-off of these activated responses [6, 10, 14].

When the brain perceives/senses an experience or stimulus as stressful, physiologic and behavioral responses (i.e., stress responses) are initiated, leading to allostasis and adaptation (i.e., adaptive/allostatic stress responses) [7, 14]. The goal is to keep balance, self-organize, and maintain autonomy under challenge, and ultimately to survive [6]. As a result of this ongoing adaptation, over time, allostatic load can accumulate, and the overexposure to neural, endocrine, and immune stress mediators can have adverse effects on various organ systems, leading to the onset or progression of diseases [6, 10-12, 14].

Today, two molecules that play a major role in the stress response are thoroughly examined and their functions well-known. Each molecule represents one arm of the response (the hypo-
Endogenous reward mechanisms and their importance in stress reduction, exercise and the brain

Research has identified a biological mechanism mediating behavior motivated by events commonly associated with pleasure. This mechanism is called reward. It is usually governing normal behavior through pleasurable experiences [20, 21]. Pleasure, however, describes a 'state or feeling of happiness or satisfaction resulting from an experience that one enjoys' [20]. Pleasure is a subjective phenomenon, i.e., subjective quality. Hence, an intimate association between reward and pleasure exists [20, 21]. In neurobiology, pleasure is a competence or function of the reward and motivation circuitries that are imbedded in the central nervous system (CNS). Anatomically, these reward pathways are particularly linked to the brain's limbic system. The underlying physiology, however, is complex and morphological correlates are still a matter of thorough research.

Motivation can be divided into two categories, i.e., appetitive and aversive motivation. Appetitive motivation concerns behavior directed towards goals that are normally associated with positive hedonic, i.e., pleasurable, processes (food, recreational drugs, sex etc.). In contrast, aversive motivation involves getting away from hedonically unpleasant conditions [21, 22]. Consequently, two fundamental forces rule motivation: pleasure and pain. It has been suggested that pleasure may be associated with benecception, events that facilitate survival and thus benefit the organism or species from an evolutionary biology perspective [23]. Pain, on the other hand, is associated with nociception. This latter term basically describes conditions that may have undesirable biological consequences for an organism [21, 23]. However, the illustrated division of pleasure and pain in reference to their possible biological functions and outcome should not lead to an incorrect understanding, since both conditions – in specific situations – may have the capacity to serve survival likewise. Thus, pain and pleasure potentially merge into another. With regard to specialized brain compartments involved in motivational processes, the physiological substrate for appetitive or aversive motivation (as for reward and avoidance) primarily lies within the limbic system [20, 24].

A crucial component of CNS reward and motivation circuitries are nerve cells that originate in the ventral tegmental area (VTA), near the base of the brain. These cells send projections to target regions in the frontal brain, most notably to a structure deep beneath the frontal cortex, i.e., nucleus accumbens [26, 27]. The essential neurotransmitter of this connection is dopamine. Clearly, the VTA or mesolimbic dopamine system represents a rather old but very effective part of motivational physiology and behavior. However, in humans, the reward circuit is more complex, and it is integrated with several other brain regions that serve to enrich an experience with emotion (as an example) and direct the individual’s response or behavior toward rewarding stimuli, including food,
sex and social interaction [20]. The amygdala, for instance, is a special part of limbic and reward systems that is closely related to emotion (especially fear) and has many post-synaptic receptors for which γ-aminobutyric acid (GABA) is an inhibitory neurotransmitter [20, 25]. Diazepam and other anxiolytics mimic the action of GABA at this site. Researchers have hypothesized that pleasurable experiences like various complementary medical treatments, e.g., acupuncture or meditation, may exert calming effects via release of GABA in the amygdala and other limbic areas [5, 19, 20, 25]. This speculative aspect may be supported by recent findings that link endogenous morphine production to limbic structures and complementary or alternative medicine (CAM) [5, 16-20, 25]. In fact, morphine is endogenously synthesized via dopamine, and dopamine is another key transmitter found in the amygdala [5, 17, 20, 28]. Thus, on the neurochemical level, pleasure may involve substances that possess calming and anxiolytic capacities, thereby facilitating feelings of well-being and relaxation.

The amygdala also helps to assess whether an experience is pleasurable or aversive (and whether it should be repeated or avoided) and further helps to forge connections between an experience and other cues [26, 27]. Meanwhile, the hippocampus participates in recording memories of an experience, including where, when and with whom it occurred [20]. The frontal cortex, however, coordinates and processes all this information and consequently determines the ultimate behavior. Finally, the VTA-accumbens pathway acts as a measuring tool and regulator of reward: it ‘tells’ the other brain centers how rewarding an activity is [20]. The more rewarding an activity is deemed, the more likely the individual is to remember it well and repeat it.

With regard to frequent neuronal reward ‘tracks’ within the CNS, activation of the medial forebrain bundle (MFB), as it courses through the lateral hypothalamus to the ventral tegmentum, has been shown to produce robust rewarding effects. Dopamine is substantially involved. Electrophysiological and neurochemical techniques revealed: CNS stimulation may activate a descending component of the MFB which is synaptically coupled at the ventral tegmentum to the ascending mesolimbic dopamine system, i.e., nucleus accumbens [20, 21, 29]. Pleasure-inducing electrical stimulation thus involves a circuitous reward pathway, first activating a descending MFB component and then the ascending mesolimbic dopamine pathway. Clearly, we can speak of brain’s reward and motivation circuitries.

Taken together, the brain possesses specialized pathways that mediate pleasure, reward and motivation. Psychomotor stimulants and opiates, similar to experimental electrical stimulation, activate this reward system by their pharmacological actions in the VTA and nucleus accumbens [20, 26, 27, 29]. Ventral tegmental activation, however, as well as other essential CNS reward features involve dopamine signalling. Other neurotransmitters (e.g., GABA, glutamate, serotonin, stress hormones) may play a critical role too [5, 20]. In addition, endogenous morphine/opioid peptide production may be of importance [5]. Natural rewards like food and sex in accordance with other substances, such as caffeine, ethanol, nicotine etc., may also activate brain’s reward and motivation circuitries [29]. However, the primary access to this system, at least from a biological perspective, seems to happen via endogenous or self-regulative behaviors and activities [5].

Stress reduction, exercise, brain

Exercise can reduce obesity, depression, and/or stress, to only name a few inter-correlations of substantial medical significance (e.g., see [5, 6, 30]). Physical activity, particularly aerobic exercise, can improve a number of aspects of cognition and bodily performance [31-33]. Dynamic physical activities, but not static tasks or sedentary lifestyles, lead to a marked increase of regional cerebral blood flow [34-37]. Lack of physical activity, especially among children, is a major cause for obesity and the early onset of many diseases and consecutive aggravation in adult life, e.g., cardiovascular or metabolic [31, 38]. However, there is substantial evidence mounting up that suggests exercise not only to be highly recommendable for keeping and enhancing physical health, but also to improve academic and mental performance, i.e., ‘running makes smart’ [31-33, 39]. We suggest that this effect may, in parts, be attributed to the endogenous stress reduction and protection potential, and a related neurobiological involvement of limbic portions of the brain as well as the underlying molecular pathways, already displayed above.

Physical activity is a lifestyle factor that leads to increased health and stress hardness throughout life [5, 31, 32, 35-37, 40]. It’s good to start early and not give up this practice while growing up. However, even the physical and mental decline of the elderly is not completely inherent or predestined, only reliant on genes or ‘fate’, but instead, partly reversible. Yet, these age-dependent processes can be delayed, some prevented, compensated, or even reversed, ‘just’ by starting to get active again during old age [32, 37, 39-41]. The critical aspect for this potential is the life-long ability of the brain to adjust and adapt, actually on the molecular level, and this capacity can be trained, i.e., neuroplasticity [5, 41].
A very capable training stimulus therefore seems to be mild and manageable mental stimulation or mild aerobic exercise [5, 35, 37, 39-41]. This neuroplastic effect of exercise therapy also works with stroke patients, demonstrating it as an effective life or survival strategy [42, 43].

Appropriate lifestyle interventions or purposeful activities can positively influence the reserve capacity of aging humans and the aging process itself, particularly with regard to physiological development, cognitive performance, longevity, as well as the onset and course of chronic diseases, including stress regulation (Figure 1). Cognitive development and state are plastic, i.e., flexible, facilitated by positive or pleasurable behaviors (see above) and activities, cognitive as well as physical [32]. Clearly, body and mind are interconnected [5, 37, 44-49]. For using this capacity, it is important to train cognitive and physical flexibility likewise, which seems to be true for stress management (SM) as well [6, 33, 44, 50]. However, the effect of physical activity on cognitive function, particularly but not exclusively in the elderly, turns up to be eminently impressive [5].

Physical exercise improves learning. Obviosly, this effect is based upon the enhancement of neurogenesis in the hippocampus through bodily activity, a brain area critical for learning and memory, particularly with regard to the declarative long-term memory, and it is part of the limbic brain [12, 39, 51, 52]. Clearly, there exists a positive neurobiological correlation between running and neurogenesis [51]. Interestingly, the hippocampus is also extremely sensitive to stress, since psychosocial or mental stress, in particular, tend to deteriorate neurons in the hippocampus, leading to accelerated neurodegeneration and possibly dementia [12, 53, 54]. As with stress, aging causes hippocampal decline [39]. This negative effect of stress – and aging – is potentially counteracted by exercise. In fact, stress has a direct impact upon the production/release of brain-derived neurotrophic factor (BDNF), which itself is strongly linked to the serotonin system and plays an essential role in mood and memory processes [50, 52]. More precisely, stress decreases BDNF levels, particularly in the prefrontal cortex where the working memory is located [50]. Moreover, brain tryptophan levels and serotonin metabolism correlate positively with BDNF in both prefrontal cortex and hippocampus, again highlighting the close interconnection and commonality between the underlying signalling systems [5, 50]. This appears to be also true for the stress-reward-memory-opioid/opiate connection (e.g., [5, 12, 53]), although a rather complex matter and not fully understood yet.

![Figure 1](image-url)  
**Figure 1.** Stress regulation and reward – exercise influences. Further explanations and references see text  
CBT – cognitive behavioral therapy
Stress alters memory performance, and morphine interacts with this phenomenon, be it as a primary target of stress-related memory alteration or, supposedly, as a secondary back-up player, i.e., autoregulation, following a stress-related ‘narrowing’ of the memory focus and attention concentration with the putative goal of deleting every memory input that, in the moment of fight or flight (acute stress), would negatively interfere and not serve the hoped for positive outcome for the fighting individual: while stressed, new or other working memory contents are hardly learned, that is, acquired and consolidated [12, 52, 53]. However, it seems to be biologically essential to keep the ‘idea’ of a successful strategy that helped to fight the stressor in mind, and somehow accessible afterwards, so that after the fight is over, this successful strategy can become endogenously evaluated and, if positive, memorized and learned (Figure 1). Morphine seems to play a critical role in this process, for example, as a recovery or secondary back-up molecule [5, 53]. Morphine is critical for learning, and since it is chemically linked to dopamine, i.e., derived from it, it links the pleasure of an actual event (e.g., the felt ‘challenge’, which is neurobiologically related to dopamine signalling) with the positive memorization of it and positive future expectancy (i.e., placebo response) and, additionally, induces NO release – thus, it is not surprising to find morphine and NO in memory processing [5, 20, 53, 55].

As stated above, exercise enhances learning, function and neurogenesis in the hippocampus and the prefrontal cortex, e.g., via BDNF, and this cascade is negatively influenced by stress [40, 50-52, 54]. More precisely, stress decreases BDNF, exercise increases it, given as an example. In fact, stress and physical activity are neurobiological counter-players [5, 6], and stress reduction through exercise not only improves memory functions, hippocampal neurogenesis and BDNF levels, but also mood, quality of life, and overall well-being [5, 12, 52, 56]. However, this seems to apply only to moderate exercise, since prolonged and strenuous physical activity, for example, can itself cause stress and proinflammation [57-61]. Besides the prefrontal or orbitofrontal and hippocampal areas of the brain, there are other regions that also seem to be of importance in the neurobiological stress-SM-exercise-cognition relationship, e.g., temporal cortex, bilateral insula and parainsular cortex, as well as temporoparietal regions, the amygdala and anterior cingulate, yet again suggesting region-specific effects in frontolimbic brain areas that are also involved in the processing of affective states and mood [5, 36, 40, 52, 56]. Hence, stress reduction, e.g., through exercise, has been shown to involve serotonergic and especially dopaminergic and

neuropetidergic signalling in the associated brain regions [5, 33, 52]. Dopamine, for example, seems to be of particular interest here for spatial memory, concentration and positive mood, as well as for the general effectiveness of the brain performance, or the reestablishment and safekeeping of a normal brain function in the course, e.g., of exhausting (cognitive) tasks [33]. Thus, dopamine-enhancing exercises and activities appear to be suitable means to balance stress on the neurobiological level [5]. Moreover, these various signalling molecules have to be finely tuned in challenging tasks, especially when prolonged or enduring.

The chronology and sequence of stress and stress-reducing hormone or neurotransmitter release during exercise not only depends on the actual point in time of the release, but also on the concentration and half-life, i.e., kinetic pattern, of the hormone into question. For example, BDNF and cortisol differ in that they both are produced and elevated through rampent or strenuous and exhausting exercise, however, BDNF returns to base levels instantly after the exercise challenge is over, while cortisol recovers slower [60]. Furthermore, the type of exercise is essential, as noted before, with aerobic and moderate exercise being optimally suited, in fact crucial, for molecular stress reduction and health [5]. Long-term exercise, such as distant running, can lead to an euphoric state that is sometimes called ‘runner’s high’ [5], enabling the runner to proceed with the task, though exhausting. The neurochemical correlates of this exercise-induced positive mood change critically build on opioidergic mechanisms in the brain, that is, opioid receptor activation, preferentially in prefrontal and limbic and paralimbic brain structures [5, 56]. The runner’s high phenomenon is an obvious result of autoregulatory opioid signalling [5]. The opioid peptides β-endorphin and Met-enkephalin with its precursor proenkephalin originate from the anterior pituitary, where proopiomelanocortin (POMC) is produced, again showing the connection between this signalling system and the central stress axes, as illustrated. Interestingly, prolactin is also enhanced during and post-exercise, comparable to cortisol, however, this latter hormone is a partial dopamine inhibitor that comes consecutively (i.e., delayed) after dopamine release in the stress-exercise sequence was initiated [61], comparable to the endorphins [5]. Prolactin also originates from the anterior pituitary. The more prolactin builds up in an exercise, e.g., sexual activity, the deeper the relaxation and satisfaction later [61], comparable to the postulated dopamine-morphine sequence [5]. In other words, the greater the stress (in combination with physical activity and exhaustion), the deeper the relief and relaxation, i.e., endogenous stress reduction and reward (the ‘I did
it’ component), when successfully solving and overcoming the stressful challenge [5].

Finally, since dopamine, endocannabinoids and morphine (and even serotonin) exert their effects, in part, via NO release, it is not surprising to find substantial constitutive NO activity in exercise [5, 43, 58, 59, 62]. We surmise that this potentially protective neurobiological signalling molecule plays the role of an effector for many of the observed phenomena of autoregulation [5, 58]. For example, positive results with exercise therapy in stroke patients are abolished by the inhibition of NO signalling [43]. Moreover, NO counteracts NE, that is, cellular stress, on the neuronal level, thereby explaining a self-regulatory anti-stress capacity of NO-enhancing activities [5, 6, 57, 58].

Taken together, we hypothesize that exercise induces autoregulatory stress reduction via limbic pleasure and reward pathways, using, at least in parts, the same neurobiological components like other SM tools. Positive activities and cognitive behaviors (‘thoughts’) as well as moderate physical exercises neurobiologically project on the hypothalamus and the pituitary gland, i.e., the central stress axes, via prefrontal/frontolimbic pathways, thereby inducing a central vegetative stress reduction, making it possible to mentally (i.e., self-regulatory, deliberately) influence stress and autonomous functions throughout the body, e.g., mind-body medicine [48, 49]. Stress hormones, including NE, cortisol and corticotropin-releasing hormone (CRH), get reduced, or their effects antagonized on the receptor level, while dopamine, opioids and opiates are endogenously enhanced, that is, their signalling systems initiated [5]. Serotonin and dopamine improve physical endurance capacities and stress hardness, as do the endorphins, subsequently, with endogenous morphine presumably playing a role in the recovery phase of stress and/or strenuous exercise [5]. The latter substances also improve mood and pain resistance, two critical features of a successful stress autoregulation [47]. All these effects are potentially plastic, that is, learnable and modifiable. However, research in this area has just begun to reveal the underlying potential. The basic science and methodology is complex: this may be due to the fact that measuring NO in vivo (i.e., real-time), for example, is technically challenging, and additionally, human brain tissue for morphine detection is not easy to obtain, and non-invasive (particularly: molecular) brain imaging determinations are still expensive [63-66]. Finally, the effects in question, though principally measurable, are sometimes rather subtle and, at times, difficult to interpret, or even unexpected, and thus some research still waits for confirmation by independent research groups [5, 6, 67, 68].

Conclusions

Stress is a problem of our time. This is not only true for clinical or medical settings, but also for the work environment. Stress can facilitate illness (‘disease’) and is responsible for a surge in medical spending for the treatment of, e.g., cardiovascular diseases, as well as for lower profits and higher absenteeism rates in the business world. Thus, besides clinical and external sources of stress and reasons for it, particularly psychosocial and their treatment, the endogenous or behavioral reduction and therapy of stress is still much-needed.

Research has suggested different ways and approaches to self-treat stress or buffer against stressors and their impacts. These self-healing or self-care-centred approaches are sometimes referred to as mind-body medicine or stress management strategies. They consist of various cognitive behavioral techniques, as well as relaxation exercises and nutritional counselling or therapy. However, a central part of all modern stress management programs are exercise practices.

At the core, all these approaches combine different elements to reduce stress or learn to cope with it, therefore relying on endogenous resources for health and resistance (i.e., resilience). With regard to the brain and underlying neurobiological mechanisms and pathways, endogenous reward and motivation circuitries that are imbedded in the limbic regions of the brain are responsible for the autoregulatory and endogenous reduction of stress. Exercise techniques clearly have an impact upon these systems. This is one of the reasons why physical activity not only improves overall physical health and strength, or physiologically reduces stress, but also increases mood and decreases psychological distress, i.e., depression or affective instability, by pleasure induction.

Our brain-dependent autoregulation critically relies on an orchestra of effective – and subjectively rewarding – signalling molecules to alter stress, e.g., endogenous morphine and coupled NO pathways. In combination with the pleasurable experience of a rewarding activity, which is additionally associated, for example, with the release of dopamine in the initial phase, these stress-altering actions and coupled neurobiological mechanisms represent a finely tuned autoregulatory ‘slope’, that is, an endogenous potential for stress reduction and improvement of health and facilitation of prevention. Evolutionarily and biologically, the various activities and pathways, as depicted in this work, are linked together, which can also be demonstrated by the fact that dopamine is endogenously and, by enzymatic processing, converted into morphine. Additionally, morphine signalling leads to enhanced NO release by the constitutive NO synthases.
