Abstract

Residues Tyr59, Gly78, Ser79, Met103, Gln107, Ile136 and Glu137 in human arsenic (+3 oxidation state) methyltransferase (hAS3MT) were deduced to form a potential hydrogen bond network around S-adenosylmethionine (SAM) from the sequence alignment between Cyanidioschyzon merolae arsenite S-adenosylmethyltransferase (CmArsM) and hAS3MT. Herein, seven mutants Y59A, G78A, S79A, M103A, Q107A, I136A and E137A were obtained. Their catalytic activities and conformations were characterized and models were built. Y59A and G78A were completely inactive. Only 7.0% and 13.8% inorganic arsenic (iAs) was transferred to monomethylated arsenicals (MMA) when M103A, Q107A and I136A were used as the enzyme. The $V_{\text{max}}$ (the maximal velocity of the reaction) values of M103A, Q107A, I136A and E137A were decreased to 8%, 22%, 15% and 50% of that of WT-hAS3MT, respectively. The $K_{\text{MAs}}$ (the Michaelis constant for SAM) values of mutants M103A, I136A and E137A were 15.7, 8.9 and 5.1 fold higher than that of WT-hAS3MT, respectively, indicating that their affinities for SAM were weakened. The altered microenvironment of SAM and the reduced capacity of binding arsenic deduced from $K_{\text{MAs}}$ (the Michaelis constant for iAs) value probably synergetically reduced the catalytic activity of Q107A. The catalytic activity of S79A was higher than that of WT despite of the higher $K_{\text{MAs}}$, suggesting that Ser79 did not impact the catalytic activity of hAS3MT. In short, residues Tyr59 and Gly78 significantly influenced the catalytic activity of hAS3MT as well as Met103, Ile136 and Glu137 because they were closely associated with SAM-binding, while residue Gln107 did not affect SAM-binding regardless of affecting the catalytic activity of hAS3MT. Modeling and our experimental results suggest that the adenine ring of SAM is sandwiched between Ile136 and Met103, the amide group of SAM and As-binding sites is a prerequisite for understanding the methylation of arsenic via hAS3MT.

Introduction

S-adenosylmethionine (SAM), which is a conjugate of nucleotide adenosine and amino acid methionine, is an essential metabolic intermediate in every organism having several SAM-dependent enzymes [1-4]. One of the important biological roles of SAM as a cofactor is the transfer of its methyl group to different substrates, such as lipids, proteins, DNA and other small molecules (inorganic arsenic, chloride, bromide) [5-8]. All these methylation processes catalyzed by SAM-dependent methyltransferases significantly affect various essential biological processes including biosynthesis, protein repair, signal transduction, metabolism and detoxification [9,10]. The methylation of arsenic catalyzed by arsenic (+3 oxidation state) methyltransferase (AS3MT) is considered to be the major metabolism pathway of arsenic [11,12]. Besides AS3MT, the arsenic methylation process needs trimethyloxalylphosphine hydrochloride (TECP), glutathione (GSH) or coupled reducing systems as the reductant and SAM as the methyl donor [12-16]. Mechanisms of arsenic methylation have been studied for many years [16,17], but those of the methyl transfer from SAM to As atom have not been studied. Discovery of SAM and As-binding sites is a prerequisite for understanding the methylation of arsenic via hAS3MT.

Active and As-binding sites in AS3MT have been studied in earlier studies. Residues Cys157 and Cys207 in recombinant mouse AS3MT, Cys156 in rat AS3MT, Cys156 and Cys206 in human AS3MT (hAS3MT) and Cys72, Cys174 and Cys224 in Cyanidioschyzon merolae arsenite S-adenosylmethyltransferase (CmArsM) have been verified to be the As-binding sites and in the active sites of mouse, rat, human and cyanidioschyzon merolae AS3MT, respectively [18-21]. However, most of the SAM-binding sites in hAS3MT have been deduced from the sequence alignment between diverse species AS3MT [2,11,22,23]. Only the function of the acidic residues of hAS3MT in the predicted SAM-binding motifs has been studied [24].

The residues in CmArsM, which form a potential hydrogen bond network around SAM deduced from the crystal structure of CmArsM-SAM, are Y70, G91, C92, D115, M116, Q120, I151, F223, C224, Y225 and D228. These residues can be considered the conserved As-binding sites in AS3MT, and the hydrogen bond network around SAM formed by these residues is the key to understanding the methylation of arsenic via AS3MT.

E152 and C174 [25]. The corresponding residues in hAS3MT are Y59, G78, S79, D102, M103, Q107, I136, and E137. The functions of other residues have not been demonstrated. In order to determine whether residues Y59, G78, S79, M103, Q107, I136, and E137 bind to SAM, herein we designed seven mutants Y59A, G78A, S79A, M103A, Q107A, I136A, and E137A to site-directed mutagenesis. The catalytic activities of the mutants were determined by high performance liquid chromatography-induc-tively coupled plasma-mass spectrometry (HPLC-ICP-MS), the standard curve was used to determine protein concentration [29].

**Materials and Methods**

_Caution_ Arsenical compounds are human carcinogens and should be handled accordingly [26].

**Materials**

Expression host, _Escherichia coli_ BL21 (DE3) pLysS, was bought from Novagen. Restriction enzymes, dNTPs and PrimerSTAR HS DNA polymerase, were obtained from Takara. Wild-type hAS3MT expression plasmid, pET-32a-hAS3MT, was derived from an earlier study [27]. SAM, GSH, isopropyl β-D-thiogalactopyranoside (IPTG) and bovine serum albumin (BSA) were purchased from Sigma. Arsenicals were bought from J&K Chemical Ltd. Phosphate-buffered saline (PBS, pH 7.0) buffer was prepared by mixing appropriate volumes of Na2HPO4 and NaH2PO4 into a 25 mM stock solution.

Stock solutions, which contained 25000 μg/L of the following arsenic species each, were prepared using Milli-Q deionized water with Na2AsO3 (As3+), Na2HAsO4.7H2O (As5+), disodium methylarsonate (MMA2+) and dimethylarsenate acid (DMA2+) (J&K Chemical Ltd.). All of the four stock solutions were stored at 4 °C in the dark, by which the working solutions of standards were prepared fresh daily.

**Preparation of hAS3MT mutants**

Tyr59, Gly78, Ser79, Met103, Gln107, Ile136 and Glu137 were mutated to Ala by site-directed mutagenesis using the wild type pET-32a-hAS3MT plasmid as a template [20,27]. The primers used for site-directed mutagenesis were summarized in Table 1. The PCR product was transformed into _E. coli_ Top10 (Invitrogen) E. coli expression host. Protein expression and purification were performed according to the protocols described previously [27]. The method of Bradford based on a BSA standard curve was used to determine protein concentration [29].

doi:10.1371/journal.pone.0076709.g002

Enzyme activity assays

The steady-state activity of the mutants was determined with an assay system (100 μl) containing 11 μg enzyme, 7 mM GSH, 1 mM iAs^{3+} and 1 mM SAM in PBS (25 mM, pH 7.0) by HPLC-ICP-MS [20]. To measure the iAs^{3+} substrate kinetic, 1 mM SAM and 0.5-500 μM iAs^{3+} were used. In SAM kinetic experiments, 1 mM iAs^{3+} and 0.05-1 mM SAM were used. The reaction mixtures were incubated at 37°C for 2 h, and then terminated by adding H_{2}O_{2} to a final concentration of 3% to release the arsenicals from proteins and to oxidize all arsenic metabolites to pentavalency [16,30]. 20 μl aliquots of the samples were separated on an anion-exchange column (PRP X-100 250 mm×4.6 mm i.d., 5 μm, Hamilton) by HPLC and analyzed by ICP-MS (Elan 9000, PerkinElmer) with the flow rate of 1.0 ml/min at room temperature [31-33]. The arsenical compounds were eluted with the mobile phase of 12 mM (NH_{4})_{2}HPO_{4}, the pH of which was adjusted to 6.0 with H_{3}PO_{4}. The amounts of arsenic species were calculated with the working curves prepared using 5, 10, 25, 50 and 100 μg/L of standard arsenic species. The methylation rates were calculated as mole equivalents of methyl groups that were transferred from SAM to iAs^{3+} (i.e., 1 nmol CH_{3} per 1 nmol MMA or 2 nmol CH_{3} per 1 nmol DMA) [34]. The methylation rate follows the noncompetitive substrate inhibition equation (1): \[ V = \frac{[S]V_{max}}{K_{M} + [S]} \] and double reciprocal equation (2): \[ \frac{1}{V} = \frac{1}{V_{max}} + \frac{1}{V_{max}} [S] \] where V is the initial velocity of the reaction [pmol CH_{3} transferred/h/mg protein]; [S], the substrate (iAs^{3+}) concentration [μM]; V_{max}, the maximal velocity of the reaction [pmol CH_{3} transferred/h/mg protein].
Models of hAS3MT mutants were built by modeller9v8 utilizing the most updated protein template CmArsM (PDB code 4FR0), because both hAS3MT and CmArsM were arsenic methyltransferases in different species with similar sequences [23]. The models quality of hAS3MT mutants was estimated via QMEAN Server (http://swissmodel.expasy.org/qmean/cgi/index.cgi) [40]. Pymol was used to analyze the models of hAS3MT [41].

Results and Discussion

Expression and purification of the hAS3MT mutants

The hAS3MT mutants were expressed and purified according to the protocol described in previous studies [20, 27]. All the mutant proteins were expressed successfully. The purity of each mutant protein was confirmed to be over 90% by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) (Figure 1).

Catalytic activities of the mutants

The primary methylation index (PMI) calculated as MMA/iAs and the secondary methylation index (SMI) calculated as DMA/MMA were previously developed to characterize iAs methylation ability [42, 43]. The total arsenic (TAs) concentration was defined by summing up the concentrations of iAs, MMA and DMA because no trimethylarsine oxide (TMAO) was detected in our reaction system. According to the pathway of iAs methylation, secondary methylation can only proceed based on first methylation and parts of the first methylation products are further methylated. Therefore, to assess the first methylation ability, not only the primary but also the secondary methylation products were considered. The first methylation ratio (FMR) was defined as \( \frac{\text{MMA}}{\text{iAs} \times \text{TAs}} \) and the secondary methylation ratio (SMR) was defined as \( \frac{\text{DMA}}{\text{MMA} \times \text{MMA}} \) [44]. Using the FMR and SMR to evaluate the arsenic methylation capacity of the mutants was more logical than using the PMI and SMI [45]. Proportions of iAs, MMA and DMA (iAs%, MMA% and DMA%) were defined as iAs/TAs × 100%, MMA/TAs × 100% and DMA/TAs × 100%, respectively [44]. Proportions of arsenic species and the two methylation indices, FMR and SMR were calculated to evaluate the arsenic methylation capacity of the mutants Y59A, G78A, S79A, M103A, Q107A, I136A and E137A (Figure 2a and Figure 2b). Mutants Y59A and G78A were completely inactive owing to

Values represent the average ± S.D. of three independent experiments performed by three independently purified proteins. ATR-FTIR spectra were detailed in previous literature [20, 38–39].
the absence of methylated arsenic. The proportion of iAs of S79A was lower than that of WT while the FMR and SMR of S79A were higher than that of WT, which indicated that the methylation capacity of S79A was stronger than that of WT. Only 7.0%, 10.6%, 13.8% iAs was transformed to MMA when M103A, Q107A and I136A were used as the enzyme, which suggested that the catalytic activities of mutants M103A, Q107A, I136A and E137A were all lower than that of WT. Compared with WT, the catalytic capacity of E137A also decreased as concluded from the proportion of iAs, FMR and SMR. Thus, residues Tyr59 and Gly78 affected the activity of hAS3MT significantly whereas Met103, Glu107, Ile136 and Glu137 influenced the catalytic activity to a lesser extent, and Ser79 had no effect. The catalytic activities and kinetic properties of the mutants were investigated comprehensively. The iAs³⁺-substrate-inhibition phenomena were observed for all the active mutants in a wide iAs³⁺ concentration range (0.5–500 μM) (Figure 3a), namely the rate of arsenic methylation increased with increasing arsenic concentration (0.5–40 μM) and then decreased at higher arsenic concentration (100–500 μM). The kinetic parameters of the active mutants in Table 2 were estimated from fitting the experimental data to Eq. (1) and calculated by double reciprocal plots from Eq. (2) (Figure 3b). The data obtained from the two methods were consistent. The $K_t$ values for the iAs³⁺ of mutants S79A, M103A, Q107A, I136A and E137A were all lower than those of WT-hAS3MT ($K_t$ 3.2 μM, $K_t$ 0.7 μM, $V_{max}$ 1938 pmol/h/mg [20]). The $V_{max}$ values of M103A, Q107A, I136A and E137A were decreased to 8%, 22%, 15% and 50% of that of WT-hAS3MT respectively, while the $V_{max}$ value of S79A was higher than that of WT. The $K_{M(SAM)}$ values of M103A and Q107A were higher than that of WT. For S79A, I136A and E137A, the $K_{M(SAM)}$ values did not obviously differ from that of WT-hAS3MT. The results indicated that the affinity of mutants M103A and Q107A to iAs decreased compared with that of WT, while the abilities in binding the substrate iAs³⁺ of mutants S79A, I136A and E137A were similar to the native form.

The arsenic methylation rate increased with rising SAM concentration (Figure 4). The $K_{M(SAM)}$ values of the mutants, which reflect the ability of SAM to interact with hAS3MT, were calculated from double reciprocal plots (Figure 4) and summarized in Table 2. For the mutants M103A, I136A and E137A, the $K_{M(SAM)}$ values increased to 750.4, 426.7 and 241.9 μM, which were 15.7, 8.9 and 5.1 fold higher than the WT value (WT: 47.84 μM [20]), respectively. The data revealed that residues Met103, Ile136 and Glu137 were involved in the cofactor SAM binding, which is reflect by the reduced catalytic activity of M103A, I136A and E137A. The $K_{M(SAM)}$ of S79A was about 2 fold higher than that of WT, while the $K_{M(SAM)}$ of Q107A almost equaled that of WT though the catalytic activity of Q107A was evidently lower.

Conformation of Y59A, G78A, S79A, M103A, Q107A, I136A and E137A

Circular dichroism (CD) spectroscopy, which is a sensitive method to determine the protein secondary structure [46,47], is used to analyze the conformational change of the seven mutants (Figure 5). CD spectra showed that the intensities of the peaks (208 and 220 nm) of mutants Y59A, G78A, S79A, M103A, Q107A, I136A and E137A were more intense than those of the wild type enzyme suggesting that the conformations of mutants Y59A, G78A, S79A, M103A, Q107A, I136A and E137A were different from that of WT. The content of secondary structure of the mutants was computed by Jwse32 software with reference CD-

Yang, jwr (Table 3). Compared with WT, the contents of β-pleated sheet for all mutants except Y59A increased with those of β-turn and random coil decreasing, while the content of α-helix of Y59A increased with those of β-pleated sheet, β-turn and random coil decreasing. The data indicate that the contents of secondary structure of the seven mutants differ from those of WT, especially for Y59A and I136A. FTIR spectroscopy has also been shown to be a powerful technique to evaluate the protein structure. To further confirm the secondary structure of the mutants, we carried out ATR-FTIR assays and analyzed their amide I band spectra according to well-established assignment criteria \cite{38,48} (1610–1640 cm\(^{-1}\): β-pleated sheet, 1640–1650 cm\(^{-1}\): random coil, 1650–1658 cm\(^{-1}\): α-helix, and 1660–1700 cm\(^{-1}\): β-turn). The original and curve-fitting FTIR spectra of mutants Y59A, G78A, S79A, M103A, Q107A, I136A and E137A were shown in Figure 6. There were six component bands in the amide I bands of the mutants. The contents of each secondary structure were calculated from the integrated areas of the component bands (Table 4). The secondary structure derived from ATR-FTIR is in good agreement with those from CD spectra.

**SAM-binding sites of hAS3MT mutants**

The models of hAS3MT mutants were established using modeller9v8. The crystal structure of CmArsM with cofactor SAM (PDB code 4FR0) was used as the template. The model quality was estimated on the basis of a QMEAN scoring function acceptably ranging between 0.60 and 0.65 \cite{40}. The secondary structure arrangement of the hAS3MT model was almost identical to that of CmArsM. The sites in the SAM-binding pocket (5.0 Å around SAM) of WT-hAS3MT and mutants (Y59A, G78A, S79A, M103A, Q107A, I136A and E137A) were displayed in Figure 7 and Table 5. The SAM model-derived WT-hAS3MT showed that As-binding sites Cys156 and Cys206 were located in the SAM-binding pocket [24]. However, Cys206 was not in the SAM-binding pocket of mutant G78A, which induced complete catalytic activity loss by isolating As from S-CH\(_3\). Another residue Arg83 was not located in the 5 Å range around SAM for G78A. The structure of Gly was simpler than that of Ala, so the microenvironment around SAM and the interaction between SAM and residue 78 changed when the Gly78 was replaced by Ala. Residues Arg83 and Val161 were not located in the 5 Å range around SAM for Q107A. In mutant E137A, the residues 5 Å around SAM were disconnected from R83 and D84. Glu and Gln are hydrophilic and their side chains are amide and carboxyl group, while Ala is hydrophobic and its side chain is smaller than that of Gln and Glu. The microenvironment around SAM changed and the catalytic activity of Q107A and E137A decreased when the residues 107 and 137 were changed to Ala. Residues around SAM for mutants Y59A, S79A, M103A and I136A were the same as that for WT.

One of the crucial interactions between the SAM having cation sulfonium R\(_3\)S\(^+\) and SAM-dependent methyltransferases is the cation-π force formed between aromatic residues (e.g. Tyr, Trp and Phe) with their electron-rich π system and R\(_3\)S\(^+\) of SAM [49–52]. The cation-π interaction formed between Tyr59 and S-CH\(_3\) of SAM assists to bind, recognize SAM and distinguish cationic SAM from its analogous neutral molecule S-adenosylhomocysteine (SAH). The environment around the SAM-binding sites facilitates transfer of a methyl group from SAM to As atom. These interactions between SAM and residue 59 were destroyed when Tyr59 was replaced by Ala without electron-rich aromatic side chain, and therefore resulted in Y59A being an inactive enzyme.

SAM is bonded to CmArsM via forming hydrogen bonds and hydrophobic interactions with CmArsM residues [25]. The crystal structure of CmArsM-SAM showed that the adenine ring of SAM is sandwiched by Ile151 on one side and Met116 on the other side and forms hydrogen bonds with Ile151 and Gln152, the other hydrogen bonds also form between hydroxyl groups of ribose O2* and O3* and the side chains of Asp115 and Gln120, the carboxyl group of SAM and O\(_{\text{Cys92}}\) and O\(_{\text{Trp70}}\), and the amide group of SAM and O\(_{\text{Gly91}}\) in CmArsM, the S-CH\(_3\) group of SAM is bonded to main chain atoms O\(_{\text{Tyr59}}\) and O\(_{\text{Cys174}}\) in CmArsM with van der Waals contacts [25]. As detailed above, the residues Tyr70, Gly91, Cys92, Asp115, Met116, Gln120, Ile151, Gln152 and Cys174 in CmArsM correspond to the residues Tyr59, Gly78, Ser79, Asp102, Met103, Gln107, Ile136, Glu137 and Cys156 in hAS3MT. The results in this study and others show that the mutants Y59A, G78A, D102P, D102N and C156S are all inactive \cite{20,24}. S79A is a little more active than WT while the catalytic activity of M103A, Q107A, I136A and E137A are decreased compared with that of WT. In our models, the adenine ring is indeed sandwiched between Ile136 on one side and Met116 on the other side because their aliphatic side chains are large enough to envelope the adenine ring of SAM (Figure 8). The side chain of Ala was much smaller than that of Met103 and Ile136, the residue 103 and 136 would not envelope the adenine ring of SAM when they were replaced by Ala. Asp102 forms two hydrogen bonds with the ribose hydroxyl groups of SAM [24]. The \(V_{\text{max}}\) and \(K_{\text{M(SAM)}}\) value of Q107A shows that Gln107 also significantly affects the catalytic activity of hAS3MT but it does not relate with the SAM-binding. Cys156 with functional group –

### Table 5. Residues 5.0 Å around SAM based on the models of WT and mutants Y59A, G78A, S79A, M103A, Q107A, I136A and E137A.

| Residues around 5.0 Å of SAM |

SH, which is one of the As-binding sites in hAS3MT, also interacts with the $\text{S}^+$-$\text{CH}_3$ of SAM and helps to orient the methyl group of SAM during its approach to the arsenic lone pair. Both Gly78 and Ser79 belong to the SAM-binding motif I 74-ILDGSGSG-82 and are close to the SAM in the models (Figure 8). The amide group of SAM is hydrogen bonded to O Gly78 in hAS3MT rather than Ser79 as estimated from the activity of the G78A and S79A. According to the function of Tyr70 in CmArsM and the electron-rich characteristic of residue Tyr, we conclude that the OTyr59 in hAS3MT forming potential hydrogen bond network around SAM are presented.

Figure 8. The model of WT-hAS3MT with SAM. Only residues in hAS3MT forming potential hydrogen bond network around SAM are presented. doi:10.1371/journal.pone.0076709.g008

Wuosaama AM, Hager LP (1990) Methyl chloride transferase: a carbocation system of Tyr59 could interact with the S$^+$-$\text{CH}_3$ of SAM through van der Waals contacts, the electron-rich $\pi$ system of Tyr59 forms a cation-$\pi$ interaction with sulfonium S$^+$-$\text{CH}_3$ of SAM as well as hydrogen bonding with the carboxyl group of SAM. Therefore, the Tyr59 plays an important role in binding, recognizing, distinguishing cationic SAM from its analogous neutral molecule SAH and orienting the methyl group of SAM during its approach to the arsenic electron lone pair.

Conclusion

To study the functions of residues Tyr59, Gly78, Ser79, Met103, Glu136 and Glu137 in hAS3MT, seven mutants, Y59A, G78A, S79A, M103A, Q107A, I136A and E137A were designed. Their conformation characterized by CD and ATR-FTIR spectroscopy was different from that of WT-hAS3MT. The $K_{\text{M(app)}}$ of mutants M103A and I136A indicated that they bound to SAM less tightly than WT-hAS3MT did, leading to remarkably lowered catalytic activity. The mutant Y59A was completely inactive because the cation-$\pi$ interaction and hydrogen bond formed between SAM and residue 59 disappeared when Tyr59 was changed to Ala. The modeling results showed that As-binding sites Cys156 and Cys206 in WT-hAS3MT were located in the vicinity of SAM (5 Å around), whereas As-binding site Cys206 in mutant G78A was not, which resulted in the mutant G78A being inactive. The microenvironment surrounding SAM in Q107A was also altered, and its capacity of binding to iAs was weaker, which caused a dramatic decrease in the catalytic activity of the Q107A mutant. The catalytic activity of S79A surpassed that of WT although its $K_{\text{M(app)}}$ value was higher. Met103 and Ile136 form a sandwiched structure with the adenine ring of SAM in the center. The amide group of SAM is hydrogen bonded to O Gly78 in hAS3MT, while the hydrogen bond might not be formed between Ser79 and SAM as estimated from the activity of the G78A and S79A. The model of hAS3MT bound to the S$^+$-$\text{CH}_3$ of SAM with van der Waals contacts, the electron-rich $\pi$ system of Tyr59 could interact with sulfonium S$^+$-$\text{CH}_3$ of SAM, and the hydroxyl group might hydrogen bond with the carboxyl group of SAM. These interactions would help to bind, recognize, distinguish cationic SAM from its analogous neutral molecule SAH and orient the methyl group of SAM during its approach to the arsenic electron lone pair.
