Abstract

This paper considers the multi-parametric linear complementarity problem (pLCP) with sufficient matrices. The main result is an algorithm to find a polyhedral decomposition of the set of feasible parameters and to construct a piecewise affine function that maps each feasible parameter to a solution of the associated LCP in such a way that the function is affine over each cell of the decomposition. The algorithm is output-sensitive in the sense that its time complexity is polynomial in the size of the input and linear in the size of the output, when the problem is non-degenerate. We give a lexicographic perturbation technique to resolve degeneracy as well. Unlike for the non-parametric case, the resolution turns out to be nontrivial, and in particular, it involves linear programming (LP) duality and multi-objective LP.

1 Introduction

Given a real square matrix $M$ and a vector $q$, solving a linear complementarity problem (LCP) consists of finding two nonnegative vectors $w$ and $z$ that satisfy the conditions

$$w - Mz = q, \quad w \geq 0, \quad z \geq 0, \quad w^T z = 0.$$  \hfill (1.1)

This simply stated and well-studied problem has far-reaching applications that have been well-documented in the literature. Rather than give a survey here, the interested reader is referred to the books [22, 6].

Several authors have studied the properties of various parametric versions of this problem (e.g. [17, 2, 6, 19, 7, 26, 8]), but unless there are restrictions placed on the particular parametric LCP (pLCP) considered, it is in general unrealistic to expect an efficient computational algorithm. We here study the class of pLCPs where the matrix $M$ is sufficient\(^1\) and the right hand side (the vector $q$ in (1.1)) is allowed to vary within a given affine subspace $S$. The goal is then to compute

\(^1\)Sufficient matrices are defined in Section 3.
functions $z(\cdot)$ and $w(\cdot)$ that map from the affine subspace $S$ to a solution for pLCP (1.1) whenever one exists.

This class of pLCP includes the important cases of linear and convex quadratic programs, where parameters appear linearly in the cost and the right hand side of the constraints [22]. In recent years, there has been a great deal of interest in the control community in parametric programming due to the fact that an important class of control algorithms for constrained linear systems, called model predictive controllers (MPC), can be posed as parametric linear or quadratic programs. The offline solution of these parametric problems results in an explicit representation of the optimal control action, which in some cases allows the controller to be implemented on systems with sampling rates of milli- and micro-seconds instead of the traditional seconds and minutes [25, 14, 4]. A similar setup results when computing optimal policies in a dynamic programming framework for partially observable Markov decision processes [18].

While parametric programming is widely used for sensitivity analysis, it is also applied in several other applications. In [15] it was shown that polyhedral projection can be reduced to parametric linear programming in polynomial time and of course such projections have uses ranging from the computation of invariant sets [5] and force closures [23] to program analysis [24] and theorem proving [13]. Polyhedral vertex and facet enumeration can also be posed as projection problems, and hence solved with the proposed pLCP approach [12], which as discussed below results in an output sensitive algorithm in the non-degenerate case (although not the most efficient one for this purpose).

In [2] it was shown that if $M$ is a sufficient matrix and $S$ satisfies certain general position assumptions, then $z(\cdot)$ and $w(\cdot)$ are unique piecewise affine functions that are defined over a polyhedral partition of a convex set. There is, however, no known efficient method of testing this general position assumption a priori and in fact, it is often not satisfied even in the simplest case when the pLCP models a parametric linear program [16].

This paper extends the result of [2] by removing the restrictive and untestable general position assumption, allowing the algorithm to operate on any pLCP which is defined by a sufficient matrix and an affine subspace. This is achieved through a lexicographic perturbation technique, which has the effect of symbolically shifting the affine subspace an infinitesimally small amount and into general position. We first demonstrate that this perturbation always results in a problem that is in fact in general position and hence has the favorable uniqueness and partitioning properties discussed above. The challenge then becomes one of doing calculations in this perturbed space. The main optimization problem that arises as a result of the perturbation is a linear program that is polynomially parameterized by a positive variable $\epsilon$. The decision problem to be tackled is then the determination of the behavior of this parametric problem as the parameter $\epsilon$ tends to zero. Section 5 discusses how this problem can be converted into a multi-objective linear program, which can then be solved efficiently. The proposed technique should be applicable to other algorithms that rely on lexicographic perturbation to handle degeneracy.

The resulting algorithm has the strong property that its complexity is polynomial in the size of the input (the matrix $M$) and linear in the size of the output (the number of pieces in the piecewise-affine functions $w$ and $z$). For this reason, we call the algorithm ‘output sensitive’, although it should be noted that the complexity of the functions $w$ and $z$ can be exponential in the worst case and that this complexity result is for the lexicographically shifted affine subspace, which may be more complex than the unshifted case.

The reminder of the paper is organized as follows. Section 2 gives some basic notations and a formal definition of the parametric LCP. Section 3 provides some useful properties of pLCPs on sufficient matrices. Section 4 then presents the proposed method with a general position assumption,

---

2 General position is defined in Section 3.2.
2 Parametric LCP, critical regions and their adjacency

Let us first fix some useful notations for matrices. For a matrix $A \in \mathbb{R}^{m \times n}$ and a column index $j \in \{1, \ldots, n\}$, $A_j \in \mathbb{R}^m$ denotes the $j$-th column vector of $A$. Similarly, for a row index $i \in \{1, \ldots, m\}$, $A_i \in \mathbb{R}^{I \times n}$ denotes the $i$-th row vector of $A$. For a subset $J \subseteq \{1, \ldots, n\}$, $A_J \in \mathbb{R}^{m \times J}$ denotes the matrix formed by the columns of $A$ indexed by $J$, and for a vector $v \in \mathbb{R}^n$, $v_J$ denotes the vector formed by the components of $v$ indexed by $J$. For $I \subseteq \{1, \ldots, m\}$, we denote by $A_I \in \mathbb{R}^{I \times n}$ the matrix formed by the rows of $A$ indexed by $I$.

Given a real square matrix $M$ and a vector $q$ of size $n$, the linear complementarity problem (LCP) is to find two nonnegative vectors $w$ and $z$ that satisfy

$$
\begin{align*}
    w - Mz &= q, & w \geq 0, & z \geq 0, & w^Tz &= 0.
\end{align*}
$$

In this paper, we consider the LCP (2.2) where the right-hand side is allowed to vary within some affine subspace. Specifically, the goal is to find two functions $w(\cdot)$ and $z(\cdot)$ that solve (2.2) over a given affine subspace $S$.

**Definition 2.1.** Let $Q \in \mathbb{R}^{n \times d}$ be a matrix of rank $d$, $q \in \mathbb{R}^n$ a vector and $M \in \mathbb{R}^{n \times n}$ a matrix of order $n$. The functions $w(\cdot)$ and $z(\cdot)$ are a solution to the pLCP (2.3) if for every $\theta \in \Theta_f$, $w(\theta)$ and $z(\theta)$ satisfy the relations

$$
\begin{align*}
    w(\theta) - Mz(\theta) &= q + Q\theta, \\
    w(\theta), z(\theta) &\geq 0, \\
    w(\theta)^Tz(\theta) &= 0,
\end{align*}
$$

where $\Theta_f \subseteq \mathbb{R}^d$ is the set of feasible parameters $\theta$, that is, those for which a solution to (2.3) exists.

For the remainder of the paper we assume that the problem data $M$, $q$ and $Q$ are given and we define $A \in \mathbb{R}^{n \times 2n}$ to be the matrix $[I \ -M]$. Consider the following system of linear equality constraints in non-negative variables

$$
\begin{align*}
    Ax &= q, & x \geq 0.
\end{align*}
$$

A basis is a set $B \subseteq \{1, 2, \ldots, 2n\}$ such that $|B| = n$ and $\text{rank}(A_B) = n$; $N := \{1, \ldots, 2n\} \setminus B$ is its complement and we call $x_B$ and $x_N$ the basic and non-basic variables respectively. Every basis $B$ defines a basic solution to the linear system (2.4)

$$
\begin{align*}
    x_B &= A_B^{-1}q, & x_N &= 0.
\end{align*}
$$

A basis $B$ is called complementary if $|\{i, i + n\} \cap B| = 1$ for all $i = 1, \ldots, n$, and feasible if the associated basic solution satisfies the nonnegativity constraint in (2.4), i.e. $A_B^{-1}q \geq 0$. Every complementary feasible basis defines a solution of the LCP (2.2), by setting $(w^T, z^T) = x^T$. In the parametric case, each basis is feasible for a set of parameters, which leads to the notion of a critical region.

**Definition 2.2.** The critical region $\mathcal{R}_B$ of a complementary basis $B$ is defined as the set of all parameter values for which $B$ is feasible, i.e.,

$$
\mathcal{R}_B := \{\theta \in \mathbb{R}^d | A_B^{-1}(q + Q\theta) \geq 0\}.
$$

A complementary basis $B$ is called feasible for the pLCP (2.3) if $\mathcal{R}_B$ is nonempty.
By definition critical regions are convex polyhedra contained in the set of feasible parameters $\Theta_f$. Each feasible complementary basis $B$ defines a solution of the pLCP for each $\theta \in \mathbb{R}^B$ as
\[
\begin{bmatrix}
w(\theta) \\
z(\theta)
\end{bmatrix}_B = A_B^{-1}(q + Q\theta) \quad \text{and} \quad \begin{bmatrix}
w(\theta) \\
z(\theta)
\end{bmatrix}_N = 0,
\]
which is an affine function in $\mathbb{R}_B$. As a result, if $\Theta_f$ can be partitioned into a set of critical regions whose interiors are disjoint, then we have immediately a piecewise affine solution of pLCP (2.3) defined over these critical regions.

In this paper we define a set of conditions under which such a partitioning can be achieved and introduce an efficient algorithm for this class of problems. The algorithm is based on the tracing of a graph whose nodes are the full-dimensional critical regions and whose edges are the pairs of adjacent regions (having a $(d-1)$-dimensional intersection).

**Definition 2.3.** Two critical regions $R_1, R_2$ are called adjacent if their intersection $R_1 \cap R_2$ is of dimension $d - 1$.

**Definition 2.4.** Let $V$ be the set of complementary bases $B$ of pLCP (2.3) such that $R_B$ is full-dimensional and let $E$ be the set of pairs of bases in $V$ whose critical regions are adjacent. The graph $G := (V, E)$ is called the critical region graph of the pLCP (2.3).

The proposed algorithm enumerates all full-dimensional critical regions by tracing the above graph. This tracing requires that we are able to enumerate all neighbors of a given complementary basis. The following section discusses the properties of this graph and investigates restrictions on matrices $M$ under which the neighbor search can be done efficiently.

## 3 Well behaving matrix classes for parametric LCPs

The goal of solving a parametric LCP is to compute functions $w(\cdot)$ and $z(\cdot)$ that satisfy (2.3) for all feasible values of the parameter $\theta \in \Theta_f$. As discussed in the introduction, linear complementarity problems include a very large set of difficult optimization problems and so we cannot hope for a solution in the general case. In this section, we identify classes of LCPs that are ‘well-behaving’, or that have properties which guarantee that the algorithm given in Section 4 will find a solution.

The two key properties that will be needed are convexity of the feasible set $\Theta_f$ and the existence of a “canonical” single-valued mapping from parameters to critical regions. The latter essentially means that the relative interiors of critical regions do not intersect. In this section we will formalize these notions and discuss a well-known matrix class that has the appropriate properties when the affine subspace $S \subset \mathbb{R}^n$ of all possible right hand sides is the whole space $\mathbb{R}^n$. In Section 3.2 we will then generalize this and give conditions such that these properties still hold when the right hand side is restricted to lie in some lower-dimensional affine subspace.\(^3\)

### 3.1 Complementary cones

We begin by describing the set of right hand sides $q$ in (2.3) that are feasible for a given set of active constraints.

For any index $i \in \{1, \ldots, 2n\}$ we denote with $\bar{i}$ the complementary index of $i$, i.e. $\bar{i} = (i + n) \mod 2n$. For a set $I \subseteq \{1, \ldots, 2n\}$, the set $\bar{I}$ is defined as the set of all complementary indices of elements in $I$. A set $J \subset \{1, \ldots, 2n\}$ is called complementary if $i \in J$ implies $\bar{i} \notin J$.

\(^3\)Throughout the paper, we use the same notation regarding matrix classes as in [6] and we use the properties of each class proved there. At the end of the paper we append an auxiliary section, where the relevant definitions and theorems are mentioned.
Definition 3.1. For any complementary set $J$, the cone $C(J) := \text{cone}(A_J)$ is called a complementary cone (relative to $M$), where $\text{cone}(T)$ denotes the cone of all nonnegative combinations of the columns of a matrix $T$.

If $B$ is a complementary basis, then the complementary cone $C(B)$ is full-dimensional, and conversely if the complementary cone $C(J)$ is full-dimensional then the submatrix $A_J$ has full rank, i.e. $J$ is a complementary basis. For a complementary basis $B$, we have

$$C(B) = \{ y \in \mathbb{R}^n | A_B^{-1}y \geq 0 \}.$$ \hspace{1cm} (3.7)

In the remainder of the paper we will denote by $\beta$ the matrix $A_B^{-1}$, where $B$ is the considered basis. Therefore we will write $C(B) = \{ y \in \mathbb{R}^n | \beta y \geq 0 \}$.

One can see that for a given basis $B$, the cone $C(B)$ is the set of all right hand sides that are feasible for LCP (2.2). We are interested in LCPs that have complementary cones with disjoint interiors and so we introduce the class of sufficient matrices, which has this property.

Definition 3.2. A matrix $M \in \mathbb{R}^{n \times n}$ is called column sufficient if it satisfies the implication

$$[z_i(Mz)_i \leq 0 \text{ for all } i] \implies [z_i(Mz)_i = 0 \text{ for all } i] \ .$$ \hspace{1cm} (3.8)

The matrix $M$ is called row sufficient if its transpose is column sufficient. If $M$ is both column and row sufficient, then it is called sufficient.

Remark 3.3. We note that both positive semidefinite (abbreviated by PSD) and $P$-matrices are sufficient. For a given matrix $M$ it is possible to test in finite time whether it is sufficient, although no polynomial time test is currently known.

The class of LCPs with sufficient matrices has been studied extensively, partly because this class appears to capture all critical structures for LCPs to behave nicely. In particular, this class admits many fruitful results ranging from combinatorial algorithms and duality [11, 10] to the efficient solvability by interior-point methods [20]. We will see that this class is ideal also for the investigation of parametric LCPs. We start with a key fact.

Proposition 3.4 ([6, Theorem 6.6.6]). If $M$ is a sufficient matrix, then the relative interiors of any two distinct complementary cones are disjoint.

The union of all complementary cones forms a set known as the complementary range $K(M)$.

The complementary range is equal to the set of all right hand sides of the LCP for which a feasible solution exists [6]

$$K(M) := \{ q | \text{the LCP (2.2) with matrix } M \text{ and right hand side } q \text{ is feasible} \} \ .$$ \hspace{1cm} (3.9)

Proposition 3.5. If $M$ is a sufficient matrix, then the complementary range $K(M)$ is a convex polyhedral cone $K(M) = \text{cone}([I - M])$.

Proof. The statement follows from the fact that sufficient matrices are in $Q_0$, see Theorem A.10. \hfill \Box

Remark 3.6. Throughout the paper we will draw upon the properties of two matrix classes extensively. The first class is the $Q_0$-matrices, whose complementary range $K(M)$ is a convex cone and the second is the fully semi-monotone matrices, denoted by $E^f_0$ which have complementary cones that are all disjoint in their interiors. The class of sufficient matrices is contained in $Q_0 \cap E^f_0$ and is perhaps the largest known subclass defined by a simple set of conditions, which is why sufficiency is assumed for the majority of the results in this paper. It should be noted, however, that many of the results hold under slightly relaxed assumptions.
We will study now the adjacency relationship of complementary cones for the case of sufficient matrices. Specifically, since our goal is to compute the critical region graph \( G \), finding all neighbors of any given region is a crucial issue. We first look at the neighbors of a complementary cone that determine possible candidates for the neighbors for a critical region.

**Definition 3.7.** Two complementary bases \( B_1 \) and \( B_2 \) are called *adjacent* if their cones \( C(B_1) \) and \( C(B_2) \) are adjacent, that is, the dimension of \( C(B_1) \cap C(B_2) \) is \( n - 1 \).

The following lemma is important in narrowing down the candidates of the neighbor search.

**Lemma 3.8.** If \( M \in \mathbb{R}^{n \times n} \) is a sufficient matrix and \( B_1 \) and \( B_2 \) are adjacent complementary bases, then \( |B_1 \cap B_2| \geq n - 2 \).

*Proof.* By the definition of adjacency the intersection \( C(B_1) \cap C(B_2) \) has dimension \( n - 1 \) and therefore there exists a \( q \in K(M) \) that lies in the relative interior of a facet of both complementary cones, which means that both basic solutions \( (w_1, z_1) \), \( (w_2, z_2) \) have exactly \( n - 1 \) strictly positive components. Recall that basic solutions can be stated as:

\[
\begin{bmatrix}
  w_1 \\
  z_1
\end{bmatrix}_{B_1} = A^{-1}B_1 q , \\
\begin{bmatrix}
  w_2 \\
  z_2
\end{bmatrix}_{B_2} = A^{-1}B_2 q .
\]

Let \( J \) be a subset of \( B_1 \) such that \( (w_1^T, z_1^T)_J > 0 \) and \( |J| = n - 1 \). By Theorem A.11, we have \( (w_2^T, z_2^T)_J = 0 \). Since \( (w_2^T, z_2^T)_{B_2} \) has exactly one zero component, at least \( n - 2 \) elements of \( J \) are not in \( B_2 \) and therefore their complements are. This shows \( |B_1 \cap B_2| \geq n - 2 \). \( \Box \)

**Remark 3.9.** It can be shown for \( P \)-matrices that two bases are adjacent if and only if they differ by exactly one element. This implies that the set of all complementary cones for a \( P \)-matrix LCP together with their faces forms a polyhedral complex. Unfortunately, this polyhedral complex property is not satisfied in general for sufficient matrices, nor in fact for the proper subclass of PSD matrices. More precisely, the intersection of two critical regions may not be a common face, see [17].

**Lemma 3.10.** Let \( M \in \mathbb{R}^{n \times n} \) be sufficient and \( B \) be a complementary basis. If \( B' = B \setminus \{i\} \cup \{i\} \) is a basis then \( C(B) \) and \( C(B') \) intersect in their common facet \( C(B \setminus \{i\}) \). Moreover no other full-dimensional complementary cones intersect the relative interior of \( C(B \setminus \{i\}) \), i.e. \( C(B') \) is the unique complementary cone adjacent to \( C(B) \) along this facet.

*Proof.* Since \( B \setminus \{i\} \) is a subset of \( B \) and \( B', C(B \setminus \{i\}) \) is a common facet of \( C(B) \) and \( C(B') \). The second statement follows directly from the fact that the interior of any other complementary cone can intersect neither \( C(B) \) nor \( C(B') \), since \( M \) is sufficient. \( \Box \)

**Remark 3.11.** Lemmas 3.8 and 3.10 imply that a complementary basis has at most \( n + \frac{n^2 - n}{2} \) adjacent complementary bases.

Given a complementary basis \( B \) one can see that replacing any index \( i \in B \) with its complement \( i \) preserves complementarity, i.e. \( B \setminus \{i\} \cup \{i\} \) is still a complementary set. This operation is called a *diagonal pivot*. If we substitute two different indices \( i, j \in B \) with their complements, then the operation is called an *exchange pivot*. Lemma 3.8 ensures that for a given basis \( B \) we can reach all adjacent bases by a single diagonal pivot or by a single exchange pivot operation. However, for some \( i \in B \) the set \( B \cup \{i\} \setminus \{i\} \) may not be a basis, or for some pair \( (i, j) \in B \) the basis \( B \cup \{i, j\} \setminus \{i, j\} \) may not be adjacent to \( B \). Therefore, in order to determine whether a set given by a diagonal or an exchange pivot is in fact an adjacent feasible basis we need a further condition. Such a condition can be easily derived from the *dictionary* of the basis \( B \).
Definition 3.12. Given a complementary basis \( B \) and its complement \( N \) the matrix \( D := -A_B^{-1} A_N \in \mathbb{R}^{B \times N} \) is called the dictionary of \( B \).

We begin by examining the diagonal pivot, for which a well-known adjacency condition can be derived.

Fact 3.13. If \( B \) is a complementary basis, then for any \( i \in B \), the set \( B \backslash \{i\} \cup \{\bar{i}\} \) is a basis if and only if \( D_{i,\bar{i}} \neq 0 \).

We now consider the exchange pivot and derive necessary and sufficient conditions for adjacency, which are again based on examining elements of the dictionary.

Proposition 3.14. Let \( M \in \mathbb{R}^{n \times n} \) be a sufficient matrix, \( B \) be a complementary basis and \( D \) be its dictionary. Consider the complementary basis \( B' = B \backslash \{i, j\} \cup \{\bar{i}, \bar{j}\} \), where \( i, j \in B \) are distinct. The following condition holds:

\[
\text{dim}(C(B \backslash \{i\}) \cap C(B')) = n - 1 \iff D_{\bar{i}i} = 0 \text{ and } D_{\bar{j}i} < 0. \tag{3.10}
\]

Proof. Define \( \alpha_k := -D_{ki} \), then the following holds:

\[
A_{\bar{i}} = \sum_{k \in B \backslash \{i\}} \alpha_k A_k, \tag{3.11}
\]

Let \( j \in B \backslash \{i\} \), since \( \alpha_j \neq 0 \) (we have assumed \( B' \) to be a basis) we can rewrite (3.11) as

\[
A_{\bar{j}} = \frac{1}{\alpha_j} \left( A_{\bar{i}} - \sum_{k \in B \backslash \{i, j\}} \alpha_k A_k \right). \tag{3.12}
\]

Let us consider

\[
q(\lambda) = \sum_{k \in B \backslash \{i\}} \lambda_k A_k, \tag{3.13}
\]

which lies in the relative interior of \( C(B \backslash \{i\}) \) if and only if \( \lambda_k > 0 \) for all \( k \).

We can express \( q(\lambda) \) in following way by substituting (3.12) in (3.13):

\[
q(\lambda) = \sum_{k \in B \backslash \{i, j\}} \lambda_k A_k + \lambda_j \left( \frac{1}{\alpha_j} A_{\bar{j}} - \sum_{k \in B \backslash \{i, j\}} \frac{\alpha_k}{\alpha_j} A_k \right) \tag{3.14}
\]

\[
= \sum_{k \in B \backslash \{i, j\}} (\lambda_k - \alpha_k/\alpha_j) A_k + \lambda_j /\alpha_j A_{\bar{i}} \tag{3.15}
\]

Sufficiency: if \( \alpha_j > 0 \) then there exists a \( q(\lambda) \) that lies in the relative interior of both facets \( C(B \backslash \{i\}) \) and \( C(B \backslash \{j\}) \).

Necessity: since \( B' \) is a basis the unique way to express \( q(\lambda) \) as a linear combination of the vector indexed by \( B' \) is (3.15). If \( \alpha_j < 0 \) any \( q(\lambda) \in \text{rel int}(C(B \backslash \{i\})) \) can not lie in \( C(B') \). The case \( \alpha_j = 0 \) is impossible since we have assumed \( B' \) to be a basis.

Corollary 3.15 follows directly from the proposition above and allows the detection of the boundaries of the complementary range.

Corollary 3.15. Let \( M \in \mathbb{R}^{n \times n} \) be sufficient, \( B \) be a complementary basis and denote \( A_B^{-1} \) as \( \beta \). Consider the facet \( C(B \backslash \{i\}) \), for any \( i \in B \). The hyperplane \( \text{aff}(C(B \backslash \{i\})) = \{ y \in \mathbb{R}^n | \beta_i y = 0 \} \) defines a facet of the complementary range \( K(M) \) if and only if \( D_{\bar{i}i} = 0 \) and \( D_{\bar{i}} \geq 0 \).

Remark 3.16. Lemma 3.8 and Proposition 3.14 are valid also for column sufficient matrices (i.e. it is not necessary that \( M \) is row sufficient). Lemma 3.10 holds for all fully semimonotone matrices.
3.2 Critical Domains

We study now the parametric case where the right hand side of LCP (2.2) is restricted to lie within some affine subspace \( S := \{ q + Q\theta \mid \theta \in \mathbb{R}^d \} \). We will see, under some assumptions on \( S \), that the properties of the complementary cones discussed in the previous section still hold in this case.

**Definition 3.17.** If \( B \) is a complementary basis, then the **critical domain** \( S_B \) is the intersection of the affine subspace \( S \) with the complementary cone \( C(B) \)

\[
S_B := C(B) \cap S = \{ y \mid A_{B}^{-1} y \geq 0, y = Q\theta + q, \theta \in \mathbb{R}^d \} .
\]

(3.16)

Since we have assumed \( Q \) to be full column rank, the parametrisation \( q + Q\theta \) is an invertible function and it is not hard to see that a critical domain is the image of a critical region, i.e. \( S_B = QR_B + q \). Since the parametrisation is a bijection, \( S_B \) and \( R_B \) have the same combinatorial structure for any complementary basis \( B \). In particular, we have:

**Remark 3.18.** The inequality \( \beta_i y \geq 0 \) is redundant in \( S_B \) if and only if \( \beta_i(Q\theta + q) \geq 0 \) is redundant in \( R_B \), where \( \beta = A_{B}^{-1} \).

We now define a key assumption, which will allow the extension of the properties of complementary cones to critical domains.

**Definition 3.19.** The affine subspace \( S \) is said to lie in **general position** if for every complementary basis \( B \) the following condition holds

\[
S \text{ intersects } C(B) \Rightarrow S \text{ intersects } \text{int}(C(B)) .
\]

(3.17)

If a critical domain has dimension \( d = \dim(S) \), we simply say that it is **full-dimensional**. By the definition above, we have:

**Remark 3.20.** If \( S \) lies in a general position, then every critical domain is either full-dimensional or empty.

**Proposition 3.21.** If \( M \) is sufficient and \( S \) lies in general position, then the relative interiors of critical domains \( S_{B_1} \) and \( S_{B_2} \) are disjoint for any two distinct complementary bases \( B_1 \) and \( B_2 \).

**Proof.** The statement is a direct consequence of Proposition 3.4, i.e. \( \text{int}(C(B_1)) \) and \( \text{int}(C(B_2)) \) are disjoint, and from \( \text{rel int}(S_{B_i}) \subseteq \text{int}(C(B_i)) \) for \( i = 1, 2 \).

We denote the set of the feasible points of \( S \) by \( S_f \). By (3.9) it follows that \( S_f = S \cap K(M) \).

**Corollary 3.22.** If \( M \in \mathbb{R}^{n \times n} \) is sufficient then \( S_f \) is a convex polyhedron.

**Proof.** The statement is a direct consequence of Proposition 3.5.

If \( M \) is a sufficient matrix and \( S \) is in general position, then Proposition 3.21 and Corollary 3.22 ensure that the set \( K \) of nonempty critical domains defines a **polyhedral decomposition** of \( S_f \) in the sense that

- each member \( P \) of \( K \) is a convex polyhedron,
- \( \cup_{P \in K} P = S_f \),
- \( \dim P = d \) for all \( P \in K \), and
\[ \dim(P \cap P') \leq d - 1 \text{ for any two distinct members } P \text{ and } P' \text{ of } K. \]

It is important to note that the set \( K \) may not induce a polyhedral complex, i.e. the intersection of two critical domains may not be a common face. Nevertheless, because \( S_f \) is convex, we can define a graph structure of the decomposition which is connected.

**Definition 3.23.** Let \( V \) be the set of complementary bases \( B \) of pLCP (2.3) such that \( S_B \) is full-dimensional and \( E \) consist of edges connecting each pair of bases in \( V \) whose critical domains are adjacent. The graph \( G := (V, E) \) is called the critical domain graph of the pLCP (2.3).

As stated above, each critical domain \( S_B \) is the image of a critical region \( R_B \) under the affine map \( \theta \mapsto q + Q\theta \), and a similar statement can be make for the feasible sets \( S_f = q + Q\Theta_f \). Since for each complementary basis \( B \) the critical domain \( S_B \) and the critical region \( R_B \) have the same combinatorial structure, the critical domain graph \( G = (V, E) \) also defines the graph of critical regions and vice versa. In the discussion of the algorithm we will mostly consider only critical domains.

**Corollary 3.24.** If \( M \) is a sufficient matrix and \( S \) lies in general position, then the graph of critical domains \( G \) is connected.

**Proof.** The statement follows directly from the convexity of \( S_f = K(M) \cap S \), which implies that between every pair of critical domains there exists a path in the graph of critical domains.

In the previous section we have seen that for the case of sufficient matrices we can reach all adjacent cones from any complementary cone with a single diagonal or a single exchange pivot operation. Assuming general position of \( S \), this useful property also holds for critical domains.

**Proposition 3.25.** If \( M \) is sufficient and \( S \) lies in general position, then for any two complementary bases \( B_1 \) and \( B_2 \) that have nonempty critical domains the following holds: If \( S_{B_1} \) and \( S_{B_2} \) are adjacent in \( S \) then \( C(B_1) \) and \( C(B_2) \) are adjacent cones.

**Proof.** If \( S_{B_1} \) and \( S_{B_2} \) are adjacent critical domains, then their intersection is contained in \( C(B_1) \cap C(B_2) \). If \( C(B_1) \) and \( C(B_2) \) are not adjacent cones then there exists a complementary cone \( C \) adjacent to \( C(B_1) \) that contains \( C(B_1) \cap C(B_2) \). In this case \( C \cap S \) would be adjacent to \( S_{B_1} \) and would overlap with the relative interior of \( S_{B_2} \), which is a contradiction of Proposition 3.21.

Given a complementary feasible basis \( B \), Proposition 3.25 ensures that all the critical domains adjacent to \( S_B \) can be reached by exploring complementary bases adjacent to \( B \).
The proposed algorithm given in Algorithm 1 is based on a standard graph search procedure. It assumes a given function \( \text{neighbors}(B) \), which returns all bases whose critical domains are adjacent to that of a given basis \( B \). The validity follows immediately from the connectivity of the critical domain graph, Corollary 3.24. As input it takes a matrix \( M \) and an affine subspace \( S \) that satisfy the above assumptions, as well as an initial feasible complementary basis \( B_0 \) such that \( S_{B_0} \) is full-dimensional. The basis \( B_0 \) is flagged as “unexplored” and added to the set of discovered bases \( B \).

In each iteration of the algorithm an unexplored basis \( B \) is selected from \( B \), marked as “explored” and all bases that have adjacent critical domains are enumerated and added to \( B \), marking the new bases as “unexplored”. Once all bases in \( B \) have been explored, then we have found all bases with full-dimensional critical domains.

**Algorithm 1** Enumerate all critical domains by graph search

**Input:** A feasible basis \( B_0 \) with \( \dim(S_{B_0}) = d \), a sufficient matrix \( M \in \mathbb{R}^{n \times n} \) and an affine subspace \( S \) that lies in general position.

**Output:** The critical domain graph \( G = (B, E) \).

1: Initialise the set of nodes \( B := \{B_0\} \) and edges \( E := \emptyset \).
2: Flag \( B_0 \) as “unexplored”.
3: while there exists an unexplored basis \( B \) in \( B \) do
4: Flag \( B \) as “explored”
5: \( B_{\text{new}} := \text{neighbors}(B) \) //\( B_{\text{new}} := \text{neighbors}'(B) \) if \( S \) does not lie in general position
6: Flag each \( B' \in B_{\text{new}} \setminus B \) as “unexplored”
7: \( B := B \cup B_{\text{new}} \)
8: \( E := E \cup (B, B') \) for each \( B' \in B_{\text{new}} \)
9: end while
10: return \( G = (B, E) \)

The remainder of this section describes how the results of the previous sections can be exploited to efficiently enumerate all adjacent critical domains of a given basis, i.e., how the function \( \text{neighbors}(\cdot) \) can be properly implemented. The following section will then detail how the method can be extended so that the general position assumption can be relaxed.

### 4.1 Neighborhood computation of a critical domain

This section details a computational method that enumerates all bases that define adjacent critical domains of a given basis, i.e. how the basis is “explored”, under both Assumption 4.1 and Assumption 4.2.

The function \( \text{neighbors} \) is given as Algorithm 2. Let \( B \) be a basis whose critical domain is full-dimensional. By Proposition 3.25, each adjacent critical domain must have a \((d - 1)\) dimensional intersection with a facet of \( S_{B} \). We begin therefore by first computing all facets of \( S_B \) and then by determining the critical domains that intersect each one.

Given a complementary feasible basis \( B \) we determine which facets of \( C(B) \) define the facets of \( S_B \) by removing the redundant inequalities of \( S_B = \{y \in \mathbb{R}^n \mid \beta y \geq 0, y = Q\theta + q\} \), where \( \beta := A_B^{-1} \). The hyperplane \( h_i = \{y \mid \beta_i y = 0\}, i \in B \) intersected with \( S_B \) is a facet of \( S_B \) if there exists a \( y^* \in S_B \) such that \( \beta_j y^* > 0 \) for all \( j \in B \setminus \{i\} \) and \( \beta_i y^* = 0 \). This fact relies on the general position
assumption, Assumption 4.2. Therefore \( h_i \cap S_B \) is a facet of \( S_B \) if and only if the following LP: \[
    t^* = \max \quad t \\
    \text{s.t.} \quad -\beta_j Q \theta + t \leq \beta_j q, \quad \forall j \in B \setminus \{i\} \\
    -\beta_i Q \theta = \beta_i q
\] (4.18)

has an optimal value \( t^* > 0 \) strictly positive.

**Algorithm 2** Function \( \text{neighbors}(B) \): returns all bases whose critical domains are adjacent to \( S_B \).

**Input:** A complementary basis \( B \), the matrix \( M \) and the affine subspace \( S \). \( M \) is assumed to be sufficient and \( S \) to lie in general position.

**Output:** The set \( B \) of complementary bases, whose critical domains are adjacent to \( S_B \).

1: \( B := \emptyset \)
2: \( \beta := A_B^{-1} \)
3: \( D := -A_B^{-1} A_N \in \mathbb{R}^{B \times N} \) \hspace{1cm} //where \( N = \{1, \ldots, 2n\} \setminus B \)
4: for each \( i \in B \) do
5: \hspace{1cm} if \( \beta_i y \geq 0 \) is non-redundant in \( S_B \) then \hspace{1cm} //by solving LP (4.18)
6: \hspace{2cm} if \( D_{ii} > 0 \) then
7: \hspace{3cm} add \( B \setminus \{i\} \cup \{i\} \) to \( B \)
8: \hspace{2cm} else
9: \hspace{3cm} for each \( j \in B \) with \( D_{ij} < 0 \) do
10: \hspace{4cm} \( B'' := B \setminus \{i, j\} \cup \{i, \bar{i}\} \)
11: \hspace{3cm} if \( \dim(S_B \cap S_{B''}) = d - 1 \) then \hspace{1cm} //by solving LP (4.19)
12: \hspace{4cm} add \( B'' \) to \( B \)
13: \hspace{2cm} end if
14: \hspace{2cm} end for
15: \hspace{2cm} end if
16: \hspace{2cm} else
17: \hspace{2cm} end if
18: \hspace{2cm} end if
19: end for
20: return \( B \)

By solving LP (4.18) for each \( i \in B \) we can determine if \( C(B \setminus \{i\}) \) defines a facet of \( S_B \) or not; see Line 5 of Algorithm 2. If it does, then the goal is to determine which bases, if any, have critical domains that intersect this facet. From the previous section, we saw that there are three possible cases:

**Diagonal pivot.** If \( D_{ii} > 0 \) then the cone \( C(B') \) defined by \( B' := B \setminus \{i\} \cup \{\bar{i}\} \) is the unique complementary cone adjacent to \( C(B) \) along the facet \( C(B) \cap h_i \), due to Lemma 3.10, and therefore \( S_{B'} \) is the unique critical domain adjacent to \( S_B \) along the facet \( S_B \cap h_i \). Since \( S_{B'} \) is nonempty (as \( S_B \cap h_i \) is included in \( S_{B'} \)) it is full-dimensional by Assumption 4.2.

**Boundary of \( K(M) \).** \( C(B \setminus \{i\}) \) is a facet of the complementary range and therefore no other complementary cones intersect it. From Corollary 3.15, this is the case when \( D_{ii} = 0 \) and \( D_i \geq 0 \).

**Exchange pivot.** By looking at the dictionary \( D \) of \( B \) all complementary cones adjacent to \( C(B) \) that contain the index \( \bar{i} \) can be determined (see Theorem 3.14). However, not all such cones intersect \( S_B \) with dimension \( d - 1 \) and for this reason we need to test for each cone \( C(B'') \) adjacent to \( C(B) \)
Two-dimensional slice of a three-dimensional example. The cones $C_2$ and $C_3$ are both adjacent to $C_1$ along the same facet. However the affine space $S$ does not intersect $C_2$ and therefore $S \cap C_2$ is not adjacent to $S \cap C_1$. This situation arises in the case of an exchange pivot and requires that adjacency much be checked by solving an LP.

Figure 1: Adjacency of critical domains. See Example 1 for details.

Whether $S_{B'}$ is adjacent to $S_B$, i.e. whether the condition $\dim(S_B \cap S_{B'}) = d - 1$ holds. Now assume that the basis $B'' := B \setminus \{i, j\} \cup \{\bar{i}, \bar{j}\}$, where $j \in B \setminus \{i\}$, defines such an adjacent complementary cone according to Theorem 3.14. In order to determine whether $S_{B''}$ is adjacent to $S_B$ we can solve following LP:

$$\begin{align*}
\text{max} & \quad t \\
\text{s.t.} & \quad -\beta_k Q \theta + t \leq \beta_k q & \forall k \in B \setminus \{i\} \\
& \quad -\beta_k' Q \theta + t \leq \beta_k q & \forall k \in B'' \setminus \{j\} \\
& \quad -\beta_i Q \theta = \beta_i q \\
& \quad -\beta_{i}'' Q \theta = \beta_{i}'' q ,
\end{align*}$$

(4.19)

where $\beta = A^{-1}_B$ and $\beta'' = A^{-1}_{B''}$. As in the simpler case (4.18) above, the intersection $S_B \cap S_{B''}$ has dimension $d - 1$ if and only if the optimal value of (4.19) is strictly positive. In this case $S_{B''} = C(B'') \cap S$ is nonempty and by the general position assumption, it is also full-dimensional.

**Remark 4.3.** Since $\mathcal{C}(B)$ and $\mathcal{C}(B'')$ are adjacent cones and the hyperplanes $\{y | \beta_i y = 0\}$ and $\{y | \beta''_j y = 0\}$ defines their shared facet, the two hyperplanes must be equivalent. Therefore in (4.19) one of the equality constraints $-\beta_{j}'' Q \theta = \beta_{j}'' q$ or $-\beta_i Q \theta = \beta_i q$ can be removed.

**Example 1.** In Figure 1(a) a two-dimensional slice of three, three-dimensional cones is shown. The cones $C_2$ and $C_3$ are both adjacent to $C_1$ along the same facet. However the affine subspace $S$ does not intersect $C_2$ and therefore $S \cap C_2$ is not adjacent to $S \cap C_1$.

In Figure 1(b) we consider the complementary basis $B_1 = \{1, 2\}$ and the cone $\mathcal{C}(B_1) = \text{cone}(I) = \{y \geq 0\}$. The goal is to find the critical domain that is adjacent to $S_{B_1} = \mathcal{C}(B_1) \cap S$. The inequality $y_1 \geq 0$ is not redundant in $S_{B_1}$ and therefore the hyperplane $h_1 = \{y_1 = 0\}$ defines a facet of $S_{B_1}$. Since cone($-M_1, I_2$) $\cap h_1$ is equal to $\mathcal{C}(B_1) \cap h_1$, we have that cone($-M_1, I_2$) $\cap S$ is adjacent to $S_{B_1}$. The other inequality $y_2 \geq 0$ is redundant in $S_{B_1}$ and therefore the critical domain cone($I_1, -M_2$) $\cap S$ is not adjacent to $S_{B_1}$.
5 Extension of the algorithm for $S$ not in general position

The previous section presented an algorithm that enumerates all feasible bases and returns the graph of critical domains. The algorithm works only under the assumption that the image of the parametrisation $S$ lies in general position; Assumption 4.2. However, this assumption is not realistic and it is highly desirable to remove it.

In the case of degeneracy (i.e. $S$ is not in general position), Propositions 3.21 and 3.25 are no longer valid, as can be seen in Example 2. Therefore, during neighborhood computation it is not sufficient to explore only the adjacent complementary cones. In order to extend the algorithm to the degenerate case, we apply a symbolic perturbation technique (the lexicographic perturbation) which has the effect of shifting $S$ into general position.

The next subsection will demonstrate how to handle the perturbation for neighborhood computation, in particular lines 5 and 11 of Algorithm 2. By using this technique we obtain a graph of critical domains $G^\varepsilon$ relative to the perturbed affine subspace $S^\varepsilon$, which can differ from the graph of critical domains $G$ relative to $S$. In particular, some full-dimensional critical domains in $S^\varepsilon$ may be non full-dimensional in $S$. We will see that there exists a subgraph $G$ of $G^\varepsilon$ that is a graph of critical domains relative to $S$ and which can be obtained by postprocessing $G^\varepsilon$.

Example 2. This example demonstrates the effect when a parametric LCP is not in general position. Consider the parametric LCP defined by the matrices

$$M = \begin{bmatrix} 1 & -1 \\ 1 & 1 \end{bmatrix}, \quad Q = \begin{bmatrix} 1 \\ -1 \end{bmatrix} \quad \text{and} \quad q = \begin{bmatrix} 0 \\ 0 \end{bmatrix}.$$ 

A figure depicting the complementary cones relative to $M$ and of the affine subspace $S$ is shown in Figure 5. Let $B_1 = \{1, 2\}, B_2 = \{2, 3\}, B_3 = \{3, 4\}$ and $B_4 = \{1, 4\}$. For notational simplicity, we denote by $C_i = C(B_i)$ the complementary cones and by $S_i = S \cap C_i$ for $i = 1, \ldots, 4$ the critical domains. Clearly $S$ does not lie in general position because it intersects $C_1, C_3$ and $C_4$ on their boundary but not in their interiors. Proposition 3.21 is violated because $S_1$ is neither empty nor full-dimensional, and furthermore $S_3$ and $S_4$ are equal and hence $\text{rel int}(S_3) = \text{rel int}(S_4)$. Theorem 3.25 is violated because $S_2$ and $S_4$ are adjacent, but $C_2$ and $C_4$ are not.

5.1 Lexicographic perturbation

This section presents a well-known method that permits the perturbation of the image of the parametrisation $S$ into general position and which can be treated symbolically: the lexicographic perturbation.

We introduce the following notation that will be used for the reminder of the paper.

Definition 5.1. The vector $\epsilon := (\epsilon, \epsilon^2, \epsilon^3, \ldots, \epsilon^n)^T$ is called the lexicographic perturbation vector and is a function of a positive real number $\epsilon$.

We denote with $S^\varepsilon$ the affine subspace $S$ perturbed by $\epsilon$

$$S^\varepsilon := S + \epsilon = \{ y \in \mathbb{R}^n \mid y = Q\theta + q + \epsilon, \theta \in \mathbb{R}^d \}.$$  \hspace{1cm} (5.20)

Theorem 5.2. Let $M$ be a sufficient matrix and $S$ be the affine subspace $\{Q\theta + q \mid \theta \in \mathbb{R}^d\}$ for a given matrix $Q$ and a vector $q$. There exists a $\delta > 0$ such that $S^\varepsilon := S + \epsilon$ lies in general position for each $\epsilon \in (0, \delta)$. 

13
Remark 5.3. In the remainder of the paper we will use the standard expression “property A holds for all sufficiently small $\epsilon > 0$” rather than the more cumbersome “there exists $\delta > 0$ such that property A holds for each $\epsilon \in (0, \delta)$”. Therefore the claim of Theorem 5.2 can be written as: $S^\epsilon$ lies in general position for all sufficiently small $\epsilon > 0$.

To prove Theorem 5.2, we need the following lemma.

Lemma 5.4. Let $Q \in \mathbb{R}^{n \times d}$, $q \in \mathbb{R}^n$ and $S^\epsilon = \{Q\theta + q + \epsilon : \theta \in \mathbb{R}^d\}$. For any complementary cone $C$, there exist finitely many $\epsilon$ such that $S^\epsilon$ intersects $C$ but not $\text{int}(C)$.

Proof. Let $B$ be a complementary basis. We denote with $h_i$ the hyperplane $h_i := \{y|\beta_i y = 0\}$ for all $i \in B$. Therefore $C(B) \cap h_i$ is a facet of $C(B) = \{y \in \mathbb{R}^n|\beta y \geq 0\}$. We will prove that for any subset $J \subseteq B$ there are finitely many $\epsilon$ such that the following condition holds

$$\emptyset \neq S^\epsilon_B = C(B) \cap S^\epsilon \subseteq C(B) \cap (\bigcap_{i \in J} h_i) \text{ and } S^\epsilon_B \not\subseteq h_i \text{ for all } i \notin J \ .$$

(5.21)

The statement of the lemma will then follow directly, since there are finitely many subsets of $B$.

Let $J$ be any nonempty subset of $B$. For any $\epsilon$ for which (5.21) holds, $J$ contains the indices of all inequalities of $S^\epsilon$ that are implicit equalities and it holds that

$$\beta_J(Q\theta + q + \epsilon) = 0 \text{ for all } \theta \in \mathcal{R}^\epsilon_B \ ,$$

(5.22)

where $\mathcal{R}^\epsilon_B = \{\theta | Q\theta + q + \epsilon \in S^\epsilon_B\}$.

We can distinguish two cases. The case 1: there exists $i \in J$ such that $\beta_i Q$ is a zero row vector. Since $S^\epsilon_B$ is nonempty, $\beta_i(q + \epsilon) = 0$ for the condition (5.22) to be valid. This non-trivial polynomial equation holds for at most $n$ values of $\epsilon$.

Now consider the case 2: $\beta_J Q$ has no zero rows. We will prove that the matrix $\beta_J Q$ does not have full row rank. Since $S^\epsilon_B$ is nonempty and has dimension $d - \text{rank}(\beta_J Q) < d$, the Chebyshev
center problem has an optimal value of zero, i.e. \( \max\{t \mid \beta_i Q \theta - t \geq -\beta_i (q + \epsilon) \forall i\} = 0 \). We consider its dual problem

\[
\begin{align*}
\min & \quad (\beta(q + \epsilon))^T y \\
\text{s.t.} & \quad - (\beta Q)^T y = 0 \\
& \quad \sum y_i = 1 \\
& \quad y \geq 0.
\end{align*}
\] (5.23)

From strong duality, there exists a non-zero optimal solution \( y^* \geq 0 \) such that \( (\beta Q)^T y^* = 0 \) and \( (\beta(q + \epsilon))^T y^* = 0 \). We now claim that all indices of the strictly positive components of \( y^* \) are contained in \( J \). Assume that there is an index \( i \not\in J \) with \( y^*_i > 0 \). Then, for any \( \theta \in \mathbb{R}^d_B \), \( \beta_i (Q \theta + q + \epsilon) = 0 \), i.e. \( S^i_B \subseteq h_i \), which contradicts the maximality condition in (5.21). Therefore, \( y^*_i \geq 0 \) and \( (\beta Q)^T y^*_i = 0 \), i.e. there exists a non-trivial combination of rows of \( \beta_i Q \).

Let \( \{v_1, \ldots, v_s\} \) be a set of columns of \( Q \) such that \( \beta_J v_1, \ldots, \beta_J v_s \) form a basis of the column space of \( \beta_J Q \). Since \( \beta_J Q \) does not have full row rank, \( s < |J| \). If \( \beta_J (q + \epsilon), \beta_J v_1, \ldots, \beta_J v_s \) are linearly independent then for any \( \theta \in \mathbb{R}^d \) the equation (5.22) cannot hold. We claim these vectors are linearly dependent for finitely many \( \epsilon \).

First we consider the case \( s = |J| - 1 \). Then, these vectors are linearly dependent if and only if

\[
\det(\beta_J(q + \epsilon), \beta_J v_1, \ldots, \beta_J v_s) = 0.
\] (5.24)

This condition is a polynomial equation in \( \epsilon \) and holds for finitely many \( \epsilon \). Finally, if \( s < |J| - 1 \), we use the same argument by adding a proper number of vectors \( \bar{v}_1, \ldots, \bar{v}_{|J| - 1 - s} \) such that \( \beta_J v_1, \ldots, \beta_J v_s, \bar{v}_1, \ldots, \bar{v}_{|J| - 1 - s} \) are \( |J| - 1 \) linearly independent vectors.

**Proof of Theorem 5.2.** We can assume without loss of generality that \( S \) does not lie in general position. For any complementary cone \( C \) exactly one of the following cases holds:

1. \( S \) does not intersect \( C \),
2. \( S \) intersects the interior of \( C \),
3. \( S \) intersects the boundary of \( C \) and \( S \cap \text{int}(C) = \emptyset \), which can be differentiated into two subcases:
   
   a. \( \exists \delta > 0 \) such that \( C \cap S^\epsilon = \emptyset \) for all \( \epsilon \in (0, \delta) \)
   b. For all \( \delta > 0 \) there exists an \( \epsilon \in (0, \delta) \) such that \( C \cap S^\epsilon \neq \emptyset \).

For each of these cases we need to prove that there exists \( \delta > 0 \) such that either \( S^\epsilon \) intersects \( \text{int}(C) \) for all \( \epsilon \in (0, \delta) \) or \( C \cap S^\epsilon = \emptyset \) for all \( \epsilon \in (0, \delta) \). Clearly, this condition holds for cases 1, 2 and 3a. Therefore, it suffices to prove that for case 3b there exists a \( \delta > 0 \) such that \( S^\epsilon \) intersects \( \text{int}(C) \) for all \( \epsilon \in (0, \delta) \).

Let \( C \) be any complementary cone that satisfies condition 3b. From Lemma 5.4 and by assumption there exists a \( \delta > 0 \) such that \( S^\delta \) intersects the interior of \( C \) and for any \( \epsilon \in (0, \delta) \) either \( \text{int}(C) \cap S^\epsilon \neq \emptyset \) or \( C \cap S^\epsilon = \emptyset \). More precisely, one can select any \( \delta > 0 \) smaller than the smallest \( \epsilon > 0 \) for which \( S^\epsilon \) intersects \( C \) but not \( \text{int}(C) \). Since \( S^\epsilon \) shifts continuously with \( \epsilon \), there exists no \( \epsilon \in (0, \delta) \) such that \( C \cap S^\epsilon = \emptyset \). \( \square \)

**Example 3.** Figure 5.1 shows two examples in which \( S \) does not lie in general position. In the first example (Figure 3(a)) the cones \( C(\{2, 3\}) = \text{cone}(I_2, -M_1) \) and \( C(\{1, 4\}) = \text{cone}(I_1, -M_2) \) contain adjacent critical domains, although they are not adjacent cones. In the second example (Figure 3(b)) two different critical domains coincide. In higher dimensions the critical domains can overlap in
several ways and therefore it is not evident how to choose an appropriate decomposition when this situation occurs. In both cases the affine subspace $S$ can be artificially and symbolically shifted into general position through the use of lexicographic perturbation.

5.2 Neighborhood computation in $S^\epsilon$

Given a complementary basis $B$ that is feasible in $S^\epsilon$, the goal is to determine the adjacent critical domains to $S^\epsilon_B$. Since $S^\epsilon$ lies in general position, it suffices to explore the adjacent bases of the basis $B$. Similarly to the non degenerate case, we first determine the facets of $S^\epsilon_B$ at Line 5 of Algorithm 3 and then compute the adjacent critical domains that intersect with each facet.

Let $B$ be a complementary basis and consider $S^\epsilon_B = \{ y \in \mathbb{R}^n \mid \beta y \geq 0, y = Q\theta + q + \epsilon\}$, where $\beta := A_{B}^{-1}$. The hyperplane $h_i := \{ y \mid \beta_i y = 0\}$, for some $i \in B$ intersected with $S^\epsilon_B$ forms a facet of $S^\epsilon_B$ if there exists a $y^* \in S^\epsilon_B$ such that $\beta_j y^* > 0$ for all $j \in B \setminus \{i\}$ and $\beta_i y^* = 0$. Therefore $h_i \cap S^\epsilon_B$ is a facet of $S^\epsilon_B$ if and only if

$$
t^*(\epsilon) = \max \quad t
\text{s.t.} \quad -\beta_j Q\theta + t \leq \beta_j (q + \epsilon), \quad \forall j \in B \setminus \{i\}
-\beta_i Q\theta = \beta_i (q + \epsilon)
$$

has a positive optimal value for all $\epsilon > 0$ sufficiently small.
Algorithm 3 function $\text{neighbors}^\varepsilon(B)$: returns all bases whose critical domains are adjacent to $S^\varepsilon_B$.

\textbf{Input:} A complementary basis $B$, a sufficient matrix $M$ and an affine subspace $S^\varepsilon$.

\textbf{Output:} The set of complementary bases $B$, whose critical domains are adjacent to $S^\varepsilon_B$.

13: \textbf{end if}
14: \textbf{end for}
15: \textbf{end if}
16: \textbf{end for}
17: \textbf{return} $B$

This decision problem is no longer an LP, because the right hand side of the constraints depends on a polynomial in $\varepsilon$ and we want to know the behavior of $t^\star(\cdot)$ in the neighborhood of zero. In the next subsection we will propose an efficient method for determining if $t^\star(\cdot)$ is positive for sufficiently small $\varepsilon$.

If the hyperplane $h_i$ defines a facet of $S^\varepsilon_B$, then we can distinguish the same three cases as discussed in Section 4.1.

**Diagonal pivot.** If there is exactly one adjacent complementary basis $B'$, then $S^\varepsilon_{B'}$ is full-dimensional (by the general position of $S^\varepsilon$) and is the unique adjacent critical domain to $S^\varepsilon_B$ along $S^\varepsilon_B \cap h_i$.

**Boundary of $K(M)$.** If there are no adjacent complementary cones to $C(B)$ along $h_i$ (see Corollary 3.15), then there is no adjacent critical domain to $S^\varepsilon_B$ along the facet $S^\varepsilon_B \cap h_i$.

**Exchange pivot.** If there are adjacent bases $B''$ with $|B'' \cap B| = 2$ and $\dim(C(B) \cap C(B'')) = d - 1$, then we must check for each such basis $B''$ whether $\dim(S^\varepsilon_{B''} \cap S^\varepsilon_B) = d - 1$ (Line 11 of Algorithm 3).

Assume $B'' := B \setminus \{i, j\} \cup \{\bar{i}, \bar{j}\}$ where $j \in B \setminus \{i\}$. As in the non-degenerate case, we formulate a decision problem similar to LP (4.19) to test the dimension of the intersection:

$$t^\star(\varepsilon) = \max_t \quad \text{s.t.} \quad \begin{aligned}
\beta_k Q \theta - t &\geq -\beta_k(q + \varepsilon), & \forall k \in B \setminus \{i\} \\
\beta_i Q \theta & = -\beta_i(q + \varepsilon) \\
\beta'_k Q \theta - t &\geq -\beta'_k(q + \varepsilon), & \forall k \in B'' \setminus \{j\} \\
\beta_j Q \theta & = -\beta_j(q + \varepsilon),
\end{aligned}$$

\text{(5.26)}
As seen in the previous subsection, the goal is to decide whether the optimal value $t^*(\epsilon)$ of (5.25) (and of (5.26)) is positive for all sufficiently small $\epsilon > 0$. Here we introduce a method that can compute exactly the behavior of the parametric Chebyshev center problem (Lexico-positive).

### Definition 5.5

A vector $a \in \mathbb{R}^s$ is lexico-positive (denoted by $a \succ 0$), if $a \neq 0$ and the first non-zero component of $a$ is strictly positive. Given two vectors $x$ and $y \in \mathbb{R}^s$, we write $x \succ y$ if and only if $x - y \succ 0$. A matrix is called lexico-positive if all its rows are lexico-positive. If $S = \{s^i\}_{i \in I}$ is a set of vectors, then $s^j$ is the lexico minimum of $S$ if and only if $s^i \succeq s^j$ for each $i \in I$.

The following theorem demonstrates that minimizing the polynomial cost function of (5.28) is equivalent to computing the lexicographic minimum of a vector.

### Theorem 5.6

If $y$ is a feasible vector of the dual problem (5.28), then the two statements below are equivalent:

1. $\exists \delta > 0$ such that $(\beta(q + \epsilon))^T y > 0$ for all $\epsilon \in (0, \delta)$ ,
2. $(\beta|q I)|^T y > 0$.

**Proof.** The statement follows from the equality $(\beta(q + \epsilon))^T y = (1, \epsilon, \epsilon^2, \ldots, \epsilon^n)(\beta|q I)|^T y$, which holds for all $y$ and for all $\epsilon$. For every polynomial $p(x) = (1, x, x^2, \ldots, x^n)(p_0, p_1, p_2, \ldots, p_n)^T$ the following holds: there exists a $\delta > 0$ such that $p(x) > 0$ for all $x \in (0, \delta)$ if and only if the first non-zero coefficient of $(p_0, p_1, p_2, \ldots, p_n)$ is positive, i.e. $(p_0, p_1, p_2, \ldots, p_n)$ is lexico positive. 

where $\beta := A^{-1}_{B^1}$ and $\beta'' := A^{-1}_{B^0}$. The two critical domains are adjacent, i.e. $\dim(S_B^1 \cap S_B^{1'}) = d - 1$, in $S^\epsilon$ for all $\epsilon > 0$ sufficiently small if and only if $t^*(\epsilon) > 0$ for all sufficiently small $\epsilon > 0$.

### 5.2.1 Symbolic computation of the parametric Chebyshev center problem

As seen in the previous subsection, the goal is to decide whether the optimal value $t^*(\epsilon)$ of (5.25) (and of (5.26)) is positive for all sufficiently small $\epsilon > 0$. We call this decision problem a parametric Chebyshev center problem. Here we introduce a method that can compute exactly the behavior of $t^*(\cdot)$ for sufficiently small positive $\epsilon$; the proposed approach is summarized as Algorithm 4. The procedure is explained only for (5.25), since the same method can be easily applied for (5.26). The goal is to transform (5.25) into a multi-objective LP that can then be solved with any LP-solver. Recall the parametric LP (5.25):

$$
t^*(\epsilon) := \max_{t} \quad t \\
\text{s.t.} \quad -\beta_j Q \theta + t \leq \beta_j (q + \epsilon), \quad \text{for all } j \in B \setminus \{i\}
$$

(5.27)

For a fixed value of $\epsilon$, this is a linear program and its dual is:

$$
t^*(\epsilon) = \min_{y} \quad (\beta(q + \epsilon))^T y \\
\text{s.t.} \quad -(\beta Q)^T y = 0 \\
\sum_{j \neq i} y_j = 1 \\
y_j \geq 0 \quad \text{for all } j \in B \setminus \{i\} \\
y_i \quad \text{free}.
$$

(5.28)

Let us denote its feasible region by $F(i)$, that is,

$$
F(i) = \{ y \in \mathbb{R}^n | (\beta Q)^T y = 0, \sum_{j \neq i} y_j = 1, y_j \geq 0 \text{ for all } j \in B \setminus \{i\} \}.
$$

(5.29)

In order to solve (5.28) symbolically we introduce the following standard notion.

#### Definition 5.5 (Lexico-positive)

A vector $a \in \mathbb{R}^s$ is lexico-positive (denoted by $a \succ 0$), if $a \neq 0$ and the first non-zero component of $a$ is strictly positive. Given two vectors $x$ and $y \in \mathbb{R}^s$, we write $x \succ y$ if and only if $x - y \succ 0$. A matrix is called lexico-positive if all its rows are lexico-positive. If $S = \{s^i\}_{i \in I}$ is a set of vectors, then $s^j$ is the lexico minimum of $S$ if and only if $s^i \succeq s^j$ for each $i \in I$.

The following theorem demonstrates that minimizing the polynomial cost function of (5.28) is equivalent to computing the lexicographic minimum of a vector.

#### Theorem 5.6

If $y$ is a feasible vector of the dual problem (5.28), then the two statements below are equivalent:

1. $\exists \delta > 0$ such that $(\beta(q + \epsilon))^T y > 0$ for all $\epsilon \in (0, \delta)$ ,
2. $(\beta|q I)|^T y > 0$.

**Proof.** The statement follows from the equality $(\beta(q + \epsilon))^T y = (1, \epsilon, \epsilon^2, \ldots, \epsilon^n)(\beta|q I)|^T y$, which holds for all $y$ and for all $\epsilon$. For every polynomial $p(x) = (1, x, x^2, \ldots, x^n)(p_0, p_1, p_2, \ldots, p_n)^T$ the following holds: there exists a $\delta > 0$ such that $p(x) > 0$ for all $x \in (0, \delta)$ if and only if the first non-zero coefficient of $(p_0, p_1, p_2, \ldots, p_n)$ is positive, i.e. $(p_0, p_1, p_2, \ldots, p_n)$ is lexico positive. 

18
We can now consider an equivalent problem that we call a \textit{lexicographic linear program} (lexLP):

$$\text{redundancy}(B, i) : \left\{ \begin{array}{l} T^* := \text{lexmin} \ (\beta[q, I])^T y \\ \text{s.t.} \quad y \in F(i) \end{array} \right. \tag{5.30}$$

The cost of this optimization problem is vector valued and the operator \text{lexmin} means to compute the lexicographic minimum vector \((\beta[q, I])^T y\) over all feasible decision variables \(y\). We will denote this particular lexLP, which tests the redundancy of the \(i\)-th inequality in \(S'_B\), as the function \text{redundancy}(B, i).

**Theorem 5.7.** If \(t^*(\cdot)\) is the optimal value of (5.27) as a function of \(\epsilon\) and \(T^*\) is the optimal value of (5.30), then the following holds:

$$\exists \delta > 0 \text{ such that } t^*(\epsilon) > 0 \text{ for all } \epsilon \in (0, \delta) \iff T^* > 0. \tag{5.31}$$

**Proof.** The statement is a direct consequence of Theorem 5.6. \(\square\)

Note that as is the case for linear programs, the restrictions and the objective function of (5.30) are linear, although the objective returns a vector instead of a scalar. We say that \(T^*\) is the \textit{optimal value} of (5.30). If the vector \(\beta Q\) is non-zero then the feasibility region is bounded and therefore the optimal value is always attained if the problem is feasible.

For our purposes, it is not necessary to compute the entire vector \(T^*\), but only a sufficient number of its elements in order to determine if it is lexicoo-positive or not. To this end, the goal is to find the first non-zero component of \(T^*\) and therefore the lex min problem (5.30) can be treated as a multi-objective LP in the following way. First (say at step 0) we solve the LP:

$$T_0 := \min \ c_0^T y \quad \text{s.t.} \quad y \in F(i), \tag{5.32}$$

where \(c_0 := \beta q\). If \(T_0 \neq 0\) then we can conclude that the optimal value \(T^*\) of the problem (5.30) is lexicoo-positive or lexicoo-negative from the sign of \(T_0\). Otherwise, if \(T_0\) does equal zero, then we must consider the next objective function \(c_1 := \beta_1\) and minimise it while maintaining \(T_0 = 0\), and so on.

If \(T_0 = T_1 = \cdots = T_{r-1} = 0\), then at the step \(r\) we solve:

$$T_r := \min \ c_r^T y \quad \text{s.t.} \quad y \in F(i), \quad c_k y = 0, \quad k = 0, \ldots, r - 1, \tag{5.33}$$

where \(c_0 = \beta q\) and \(c_k = \beta_k\) for \(k = 1, \ldots, n\). If \(T_r \neq 0\) is the first non-zero value of \(T^* = (T_0, \ldots, T_n)\) then \(T^*\) of (5.30) is lexicoo-positive if \(T_r > 0\) and lexicoo-negative otherwise. The resulting procedure is Algorithm 4, where the feasible region of the LP (5.33) is denoted by \(F_r\).
Algorithm 4 Function isLexPositive(lexLP)

Input: A lex linear program lexLP as redundancy(·,·) (5.30) or adjacency(·,·) (5.34).

Output: Answer about lexico-positiveness of the optimal value $T^*$ of (5.30) or (5.34) respectively.

1: Let $c_0, c_1, \ldots, c_n$ be the objective functions of lexLP and $F_0$ be the feasibility region of lexLP.
2: for $r = 0$ to $n$ do
3: \( t_r^* := \min \{ c_r^T y \mid y \in F_r \} \) //by solving the LP (5.33)
4: if $t_r^* > 0$ then
5: return $T^*$ is lexico-positive.
6: else if $t_r^* < 0$ then
7: return $T^*$ is lexico-negative.
8: else
9: $F_{r+1} := F_r \cap \{ y \mid c_k^T y = 0 \}$
10: end if
11: end for

Remark 5.8. Note that the lexLP adjacency(\(B, i\)) always has a non-zero optimal value $T^*$ because zero is not feasible in (5.33) and the optimal solution $y^*$ of the last LP (5.33), with $r = n$, must be optimal also for all previous LPs. Since $\beta$ has full rank we must have that $\beta y^*$ is non-zero and therefore there must be at least one component of $T^*$ that is non-zero.

The parametric LP (5.26) that determines whether two critical domains are adjacent can also be solved using the same procedure. LP (5.26) can be rewritten as a lex min LP as follows:

\[
T^* := \begin{cases} 
\text{lexmin} & (\beta[q, I])^T y + (\beta''[q, I])^T x \\
\text{s.t.} & -(\beta Q)^T y - (\beta'' Q)^T x = 0 \\
& \sum_{k \in B \setminus \{i\}} y_k + \sum_{k \in B'' \setminus \{j\}} x_k = 1 \\\n& y_k \geq 0, \quad k \in B \setminus \{i\} \\\n& x_k \geq 0, \quad k \in B'' \setminus \{j\} \\\n& y_i, x_j \text{ free.}
\end{cases}
\]

(5.34)

We will call this lexLP adjacency(\(B, B''\)) because it tests the adjacency of $S_B$ and $S_{B''}$. Recall that one of the two equalities in (5.26) can be removed because one is redundant and therefore one of $y_i$ and $x_j$ is also redundant. Hence, (5.34) has the same structure as (5.30) and can be solved as a multi-objective LP as explained above (see Algorithm 4).

5.3 Post-processing of the graph of critical domains $G^\epsilon$

The previous section introduced a computational method for computing the graph of critical domains $G^\epsilon$ relative to the lex-perturbed space $S^\epsilon$ for all $\epsilon > 0$ sufficiently small. The goal in this section is to recover the graph $G = (V, E)$ of critical domains relative to the original space $S$ according to Definition 3.23.

The following theorems will show that one can construct from $G^\epsilon$ the graph $G$ of critical domains relative to the unperturbed space $S$.

**Theorem 5.9.** Let $M$ be a sufficient matrix, $S$ an affine subspace and consider the graph of critical domains $G^\epsilon = (V^\epsilon, E^\epsilon)$ relative to the lexicographically perturbed space $S^\epsilon$ for sufficiently small $\epsilon > 0$. Let $V$ be the set of all bases $B$ in $V^\epsilon$ with full-dimensional critical domains $S_B$. Then the following statements hold.
1. For each $B \in V^e$, the complementary cone $C(B)$ intersects $S$ and therefore $S_B$ is nonempty.

2. For any two distinct bases $B_1$ and $B_2$ in $V$, $S_{B_1}$ and $S_{B_2}$ have disjoint relative interiors.

3. The set of all full-dimensional critical domains $S_B$ for $B \in V$ covers $S_f$, i.e.,

$$\bigcup_{B \in V} S_B = S_f = K(M) \cap S,$$

and forms a polyhedral decomposition of $S_f$.

**Proof.** First, note that complementary cones are closed and so the first statement follows directly.

To prove the second, note that for all $\epsilon > 0$ sufficiently small (say $\epsilon < \delta$) $S^\epsilon$ lies in general position. From Proposition 3.25 the critical domains defined by $S^\epsilon$ are disjoint in their interiors for any positive $\epsilon < \delta$. The second statement follows from the fact that for any basis $B$, $S^\epsilon \cap C(B)$ changes continuously in $\epsilon$, for $\epsilon < \delta$.

The third statement is proven in two steps. First we prove that the critical domains whose bases are in $V^e$ define a covering of $S \cap K(M)$. Let $q \in K(M) \cap S$; since $\epsilon \in K(M)$ and $K(M)$ is a convex cone, there exists a basis $B$ such that $q + \epsilon \in C(B)$ for all $\epsilon > 0$ sufficiently small. Therefore $q$ is in $C(B)$ and hence in $S_B$ because complementary cones are closed and thus $\bigcup_{B \in V^e} S_B = S_f = K(M) \cap S$. Since critical domains are closed and $S_f$ is a convex polyhedron, the full-dimensional critical domains define a covering of $S_f$.

The above theorem demonstrates that the bases in $V^e$ have nonempty critical domains in the unperturbed space $S$. Moreover, there exists a subset $V$ whose critical domains form a polyhedral decomposition of $S_f$ according to Definition 3.23. The next theorem discusses how adjacency in $G'$ relates to adjacency in $G$.

**Theorem 5.10.** Let $M$ be a sufficient matrix and $B_1, B_2$ be two complementary bases in $V \subset V^e$, i.e. $S_{B_1}$ and $S_{B_2}$ both have dimension $d$. If $S_{B_1}$ and $S_{B_2}$ are adjacent, then there exists a path $B_1, B_2, \ldots, B_r$ in $G^e = (V^e, E^e)$ from $B_1$ to $B_2$ with the following property: $S_{B_i}$ intersects $S_{B_1} \cap S_{B_2}$ with dimension $d - 1$, i.e. $\dim(S_{B_i} \cap S_{B_1} \cap S_{B_2}) = d - 1$ for all $i = 1, \ldots, r$.

**Proof.** If $S_{B_1}^e$ and $S_{B_2}^e$ are adjacent, $(B_1, B_2)$ is clearly the desired path. We assume they are not adjacent. We choose a $\bar{q} \in \text{rel int}(S_{B_1} \cap S_{B_2})$ which is not contained in any critical domain or in any face of dimension $d - 2$ or less, and let $\theta \in \mathbb{R}^d$ be the parameter with $\bar{q} = q + Q\theta$. We look now (for a moment) at the parameter space and at the critical regions. The hyperplane $f := \{\theta | a^T \theta = b\}$ contains the intersection of the two critical regions, i.e. $f \supseteq (R_{B_1} \cap R_{B_2})$ and consider its perpendicular (normal?) line $\theta(t) = \bar{q} + t\theta$. The image of $\theta(t)$ is $q(t) = \bar{q} + tQA$ in the original space $S$, respectively $q^e(t) = \bar{q} + \epsilon + tQa$ in the perturbed space $S^e$.

We know that for each $\epsilon > 0$ sufficiently small every critical domain becomes either full-dimensional or empty. The full-dimensional ones vary continuously in function with $\epsilon$. Consider a segment $[q^e(t_1), q^e(t_2)]$ of the line $\{q^e(t) | t \in \mathbb{R}\}$ such that it intersects either $S_{B_1}^e$ and $S_{B_2}^e$ for all $\epsilon > 0$ sufficiently small. Because of the continuity no critical domain, which has dimension smaller than $d - 1$ in the original space $S$ intersects this segment for all $\epsilon > 0$ sufficiently small. Similarly, for any $B \in V^e$ no face of $S_B$ of dimension smaller than $d - 1$ intersects $[q^e(t_1), q^e(t_2)]$ for all $\epsilon > 0$ sufficiently small. The desired path is given by the critical domains which decompose the line segment between $S_{B_1}$ and $S_{B_2}$.

Note that the last condition in the above theorem, along with Proposition 3.21, implies that $\dim(S_{B_i}) = d - 1$ for $i = 2, \ldots, r - 1$ and therefore Theorems 5.9 and 5.10 imply the following corollary.
Corollary 5.11. Let \( M \) be a sufficient matrix, \( S \) an affine subspace and let \( \mathcal{G}^e = (V^e, E^e) \) be the graph of critical domains relative to \( S^e \). Then, the graph of critical domains \( \mathcal{G} = (V, E) \) relative to \( S \) is related to \( \mathcal{G}^e \) as follows:

1. \( V \subseteq V^e \)
2. For every basis \( B \in V \), \( S_B \) has dimension \( d \).
3. For each pair of bases \( B_1 \) and \( B_2 \), the critical domains \( S_{B_1} \) and \( S_{B_2} \) are adjacent if and only if there exists a path \( (\tilde{B}_1, \ldots, \tilde{B}_r) \) in \( \mathcal{G}^e \) with \( \tilde{B}_1 = B_1 \), \( \tilde{B}_r = B_2 \) and \( \dim(S_k) = d - 1 \) for \( k = 2, \ldots, r - 1 \) (or \( (B_1, B_2) \in E^e \)).

The above corollary provides a simple procedure for computing a critical region graph \( \mathcal{G} = (V, E) \) relative to the unperturbed affine set \( S \) from the perturbed one \( \mathcal{G}^e \). We begin from the perturbed critical region graph \( \mathcal{G} = (V, E) := \mathcal{G}^e \) and remove each node \( B \) from \( \mathcal{G} \) that has a critical domain \( S_B \) which is not full-dimensional and add all new edges \( (B_1, B_2) \) to \( E \) satisfying the statement 3 of Corollary 5.11. From Theorem 5.9, the critical domains of the nodes of the resulting graph will form the desired polyhedral covering of the \( S_f \). Theorem 5.10 states that the resulting graph contains edges for all adjacent bases, but may be overconnected since some of the critical domains \( S_B \) of removed bases \( B \) may have had a dimension less than \( d - 1 \). It remains, therefore, to test each edge in order to determine if the connected bases are in fact adjacent in the unperturbed space. As discussed previously, both operations for testing full-dimensionality and adjacency can be posed as linear programs.

Remark 5.12. Note that much of the computation required to test for full-dimensionality of the critical domains for the unperturbed affine set has already been done while building the perturbed graph. Specifically, one can determine if a region is full-dimensional by examining the first component \( T_0 \) of the optimizer of LP (5.30).

6 Complexity of the algorithm

In this section we will discuss the complexity of the proposed algorithm, which enumerates all full-dimensional critical domains relative to the lexicographically perturbed affine subspace \( S^e \). The well-known example by Murty (see [21] or see Chapter 6 in [22]), which was used to prove the non-polynomiality of the Lemke and the principal pivoting methods, can be easily seen to demonstrate that the number of critical domains of a pLCP with an affine subspace \( S \) of dimension 1 and \( P \)-matrix \( M \) is exponential in \( n \). Since the complexity of the graph search (Algorithm 1) is a polynomial function of the number of critical domains, no algorithm for pLCP is polynomial in \( n \). It is, however, possible to bound the number of operations required to explore the neighborhood of each critical domain, i.e. the complexity of Algorithms 2 and 3. Since each critical domain will be explored exactly once, we can say that the algorithm is output sensitive in that its complexity is a polynomial function of the number of full-dimensional critical domains and the size of input, provided that a polynomial-time algorithm for linear programming is used.

We first consider the general position case and study the complexity of Algorithm 2. Assume that \( M \) is of order \( n \), the affine subspace \( S \) is of dimension \( d \) and let \( B \) be a complementary basis with a nonempty critical domain \( S_B \). The main computations of the function \( \text{neighbors}(B) \) (Algorithm 2) are:

- Redundancy checking at Line 5
  (Solve LP (5.28) with \( n \) variables and \( d + 1 \) constraints.)
• Checking adjacency for the case of an exchange pivot at Line 11
  (Solve LP (4.19) with 2n variables and d + 1 constraints.)

We denote the time necessary to solve an LP in standard form by $T_{LP}(\text{var, eq})$, where var denotes the number of (nonnegative) variables and eq is the number of equality constraints. The time necessary to explore a critical domain can then be bounded as follows.

**Theorem 6.1.** Let $M \in \mathbb{R}^{n \times n}$ be a sufficient matrix and assume that the affine subspace $S$ lies in general position. For each complementary basis $B$ with a nonempty critical domain $S_B$ the time necessary to explore the neighborhood of $S_B$ is bounded by:

$$n T_{LP}(n, d + 1) + \frac{n^2 - n}{2} T_{LP}(2n, d + 1).$$  \hfill (6.35)

**Proof.** Redundancy checking requires the solution of LP (5.28) once for each of the $n$ inequalities of $S_B$, which takes $n T_{LP}(n, d + 1)$ time. Adjacency checking by solving the LP (4.19) is necessary only in the case that the considered adjacent basis $B''$ differs by two elements from the basis $B$ and since there are at most $\frac{n^2 - n}{2}$ such bases, the second term $\frac{n^2 - n}{2} T_{LP}(2n, d + 1)$ follows. \hfill \Box

If $S$ does not lie in general position, then the lexLPs (5.30) and (5.34) are solved instead of LPs (4.18) and (4.19). Each lexLP can be solved as a sequence of at most $n + 1$ LPs with the same variables and constraints (see Algorithm 4), which leads to the following complexity bound.

**Theorem 6.2.** If $M \in \mathbb{R}^{n \times n}$ is a sufficient matrix, then for each complementary basis $B$ with nonempty critical domain $S_B$ the time necessary to explore the neighborhood of $S_B$ can be bounded by

$$(n^2 + n) T_{LP}(n, d + 1) + \frac{n^3 - n}{2} T_{LP}(2n, d + 1).$$  \hfill (6.36)

The above theorems bound the complexity of “exploring” a basis of the output in Algorithm 1 (Line 5). The condition at Line 6, which can be verified in time bounded by the logarithm of the size of the output, ensures that each output basis is explored exactly once. As a result, the complexity of the algorithm grows linearly with the size of the output and so is output sensitive.

**7 Example**

In this section we present a simple illustrative example that arises from control theory. Consider the following discrete time constrained linear time-invariant system:

$$x^+ = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} x + \begin{pmatrix} 1 \\ 0.5 \end{pmatrix} u,$$

$$||x||_\infty \leq 5, \quad ||u||_\infty \leq 1,$$

where $x \in \mathbb{R}^2$ is the system state, $x^+$ is the successor state and $u \in \mathbb{R}$ is the system input. A common method of control for this class of systems is Model Predictive Control, in which we solve
at each point in time the following finite horizon optimal control problem:

$$J^\star(\theta) = \min \sum_{k=0}^{N-1} \left( \|Q x_k\|_2^2 + \|R u_k\|_2^2 \right) + \|Q_f x_N\|_2^2$$

subject to

$$x_{k+1} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} x_k + \begin{pmatrix} 1 \\ 0.5 \end{pmatrix} u_k$$

$$\|x_k\|_\infty \leq 5, \quad \|u_{k-1}\|_\infty \leq 1, \quad \forall k \in \{1, \ldots, N\}$$

(7.37)

where $\theta$ is the current state of the system, the prediction horizon $N$ is 5 and the weighting matrices $Q$, $R$ and $Q_f$ are the identity. For high-speed systems, such as electric power converters, the goal is to solve the above quadratic program as rapidly as possible, in some cases at rates exceeding hundreds of kilohertz (e.g. [3]). By computing the optimizer offline as an explicit piecewise-affine function of the state $\theta$, these speeds can be achieved [25, 14, 4]. The above parametric quadratic program is easily converted to a pLCP with a positive semi-definite matrix $M$ [22], which was then solved using the proposed algorithm. The resulting polyhedral partition and mapping from the parameter $\theta$ to the optimizer $u_0$ is shown in Figure 4.

8 Conclusion

In this paper an algorithm to enumerate all feasible bases of the parametric LCP defined by a sufficient matrix $M$ and a lexicographically perturbed affine subspace $S$ was proposed. It has been shown that the perturbed parametric LCP can be solved in a time linearly bounded by the size of the output and moreover, this output can be efficiently post-processed in order to generate a polyhedral decomposition for the unperturbed original affine subspace $S$.

One feature of the algorithm which is not ideal is the space requirement. Namely, the proposed algorithm must store all discovered feasible bases in the memory because it relies on the standard graph search technique. A great improvement can be made if we could apply the reverse search technique [1] which is essentially memory free. For this, it is necessary for the underlying graph to be oriented properly with exactly one sink. Somewhat similar to the present work, the paper
[9] proposed an algorithm to compute a polyhedral complex known as the Gröbner fan which was shown to have such a “reverse search property.” Finding such an orientation for the graph of critical domains is an excellent subject of the future research.

A Useful properties of matrix classes

This section gives an overview of some matrix classes with important properties for linear complementarity problems. The reader is referred to [6] for a thorough survey.

P-Matrices

**Definition A.1.** The matrix $M \in \mathbb{R}^{n \times n}$ is a P-matrix if and only if all principal minors of $M$ are strictly positive.

This class characterizes the matrices $M$ for which the corresponding LCP always has a unique solution.

**Theorem A.2.** The following statements are equivalent:

1. $M \in \mathbb{P}$,
2. The LCP defined by the matrix $M$ has a unique solution for all right hand side vectors $q \in \mathbb{R}^n$. 

3. $M$ does not reverse the sign of any nonzero vectors, i.e.
\[ z_i(Mz)_i \leq 0 \text{ for all } i \Rightarrow [z = 0]. \]

Recall that $M \in \mathbb{R}^{n \times n}$ is a positive definite matrix, denoted with $PD$ if for all $x \in \mathbb{R}^n$ it holds that $x^TMx > 0$. It is then easy to see from the above theorem that positive definite matrices belong to the class $P$.

$P_0$-matrices

Definition A.3. The matrix $M \in \mathbb{R}^{n \times n}$ is a $P_0$-matrix if and only if all principal minors of $M$ are non-negative.

Analogously to the positive-definite case above, positive-semidefinite matrices (PSD) are clearly in $P_0$. The following theorem gives properties of PSD matrices relevant to the solution of pLCPs.

Theorem A.4. Let $M \in \mathbb{R}^{n \times n}$ be a matrix and $I$ be the identity matrix of the same order. The following statements are equivalent:

1. $M \in P_0$,
2. For each vector $x \neq 0$ there exists an index $k$ such that $z_k \neq 0$ and $z_k(Mx)_k \geq 0$,
3. $(M + \epsilon I)$ is a $P$ matrix for all $\epsilon > 0$.

Semimonotone matrices

Definition A.5. A matrix $M \in \mathbb{R}^{n \times n}$ is called semimonotone if the following holds:

for all $x \geq 0, x \neq 0 \Rightarrow [x_k > 0$ and $(Mx)_k \geq 0$ for some $k]$ . (1.38)

The class of such matrices is denoted by $E_0$ and by Theorem A.4, every $P_0$-matrix is semimonotone.

Definition A.6. Let $M \in \mathbb{R}^{n \times n}$ be a semimonotone matrix. If for all index subsets $\alpha \subseteq \{1, \ldots, n\}$ with $\det(M_{\alpha\beta}) \neq 0$ the principal pivot transform of $M$ with respect to $\alpha$

\[ M' := \begin{bmatrix} M_{\bar{\alpha}\bar{\alpha}}^{-1} & -M_{\bar{\alpha}\alpha}^{-1}M_{\alpha\bar{\alpha}} \\ M_{\bar{\alpha}\alpha}M_{\alpha\bar{\alpha}}^{-1} - M_{\bar{\alpha}\alpha}^{-1}M_{\alpha\bar{\alpha}}M_{\alpha\alpha}^{-1}M_{\alpha\bar{\alpha}} \end{bmatrix} \]

is semimonotone, then $M$ is called fully semimonotone. The class of such matrices is denoted with $E_{0f}$ and $M$ is said to be an $E_{0f}$-matrix.

$Q_0$-Matrices

Definition A.7. An LCP defined by the matrix $M$ and right hand side vector $q$ is called weakly feasible if there exist positive vectors $z$ and $w$ such that $w - Mz = q$ and feasible if $z'w = 0$ also holds. The class of matrices $M$ for which the LCP is feasible whenever it is weakly feasible, is denoted by $Q_0$.

Since $P$-matrices are feasible for each vector $q$, they are also $Q_0$-matrices.

Theorem A.8. Let $M \in \mathbb{R}^{n \times n}$ and $I$ be the identity matrix of same order. The following statements are equivalent:
1. $M \in Q_0$,
2. The complementary range $K(M)$ is convex,
3. $K(M) = \text{cone}(I - M)$

The implications of convexity of the complementary range are discussed in the next section.

**Sufficient Matrices**

**Definition A.9.** A square matrix $M$ is called *column sufficient* if it satisfies the implication:

$$[z_i(Mz)_i \leq 0 \text{ for all } i] \implies [z_i(Mz)_i = 0 \text{ for all } i].$$

The matrix $M$ is called *row sufficient* if its transpose is column sufficient. If $M$ is both column and row sufficient, then it is said to be *sufficient*.

**Theorem A.10.** If $M$ is row sufficient matrix, then

1. $M \in P_0$,
2. $M \in Q_0$.

From the theorem above we have that every column sufficient matrix also belongs to $P_0$. Below we state a characterisation of column sufficient matrices, which has an important implication regarding the structure of the resulting complementary cones.

**Theorem A.11.** Given a matrix $M \in \mathbb{R}^{n \times n}$, the following statements are equivalent:

1. $M$ is column sufficient,
2. For each vector $q \in \mathbb{R}^n$ the following holds: if $(z^1, w^1), (z^2, w^2)$ are two solutions of the LCP defined by the matrix $M$ and the vector $q$, then $(z^1)^T w^2 = (z^2)^T w^1 = 0$.
