Abstract

We report the experimental observation of the recently predicted peaks on the \textit{I-V} curve of the superconducting single-electron transistor at relatively high temperatures. The peaks are due to the matching of singularities in the quasiparticle density of states in two electrodes of a tunnel junction. The energy shift due to Coulomb blockade provides the matching at finite voltage. 73.40.Gk, 73.40.Rw, 74.50.+r
Single-electron effects in superconducting structures have several additional features in comparison with that in normal metals or semiconductors. The main differences are due to the specific role of the parity of the electron number on a small island, the effects of the Josephson coupling and the specific shape of the quasiparticle density of states (QDS). The last topic received relatively small attention so far in both theoretical and experimental single-electronics, although QDS leads to various interesting effects. Besides the well-known shift of the Coulomb blockade threshold by $4\Delta/e$ in SSS single-electron transistor (SET) (by $2\Delta/e$ in NSN or SNS cases), let us mention the direct reproduction of the QDS on the $I$-$V$ curve of the SET with discrete energy spectrum of the central electrode and in the case of odd-parity current singularity-matching (SM) peaks at finite temperatures, the limitation of the differential conductance by quantum resistance and the conductance jump at $V = 4\Delta/e$ due to cotunneling.

In this paper we discuss the theory of SM peaks in more detail and report their experimental observation in the SSS SET. Somewhat similar experimental results will be presented soon by another group.

The origin of SM peaks can be easily understood from the “orthodox” theory of the SET. Let us neglect the effects due to Josephson coupling and consider only the quasiparticle tunneling. The dc current $I$ through the SET consisting of two tunnel junctions in series can be calculated from the equations

$$I = \sum_n \left[ \Gamma_1^+(n) - \Gamma_1^-(n) \right] \sigma(n),$$

$$\sigma(n) \left[ \Gamma_1^+(n) + \Gamma_2^-(n) \right] = \sigma(n + 1) \left[ \Gamma_1^-(n + 1) + \Gamma_2^+(n + 1) \right],$$

where $\Gamma_i^\pm(n)$ are the rates of tunneling through $i$th junction ($i = 1, 2$) in the positive (+) or negative (−) direction when $n$ extra electrons are present on the central electrode of the SET, and $\sigma(n)$ is the probability of the charge state $n$. In the case of $SS$ junction the tunneling rates $\Gamma_i^\pm(n) \equiv \Gamma_i(W_i^\pm(n))$ are given by equations

$$\Gamma_i(W) = \frac{1}{e^2 R_i} \int_{-\infty}^{+\infty} \rho(\varepsilon) f(\varepsilon) \rho(\varepsilon + W)[1 - f(\varepsilon + W)]d\varepsilon,$$
\[ \rho(\varepsilon) = \sqrt{\frac{\varepsilon^2}{\varepsilon^2 - \Delta(T)^2}} \theta(\varepsilon^2 - \Delta^2), \]  

(4)

where \( \rho(\varepsilon) \) is the normalized QDS, \( \Delta(T) \) is the superconducting energy gap, \( \theta(x) \) is the step function, \( f(\varepsilon) = 1/(1 + \exp(\varepsilon/T)) \) is Fermi function, \( T \) is temperature, \( R_i \) is the normal tunnel resistance of \( i \)th junction, and the energy gain \( W \) is given by

\[ W_i^\pm(n) = \frac{e^2}{C_{\Sigma}} \left[ \pm \frac{V C_1 C_2}{eC_i} - \frac{1}{2} \pm (-1)^i \left( n + \frac{Q_0}{e} \right) \right]. \]  

(5)

Here \( C_1 \) and \( C_2 \) are the junction capacitances, \( C_{\Sigma} = C_1 + C_2 \) is the total island capacitance, and \( Q_0 \) is the total background charge which accounts for the initial background charge \( Q_{00} \) and the charge induced by the gate voltage \( V_g, Q_0 = Q_{00} + V_g C_g \) (for definiteness we consider the gate capacitance \( C_g \) as being added to \( C_1 \), although an arbitrary distribution of \( C_g \) between \( C_1 \) and \( C_2 \) is possible in calculations).

At low temperatures the quasiparticle current in SSS SET appears only above the voltage threshold

\[ V_i = \min_{i,n}(V_{i,n}^{QP} | V_i > 4\Delta(T)), \]  

(6)

\[ V_{i,n}^{QP} = \frac{e C_i}{C_1 C_2} \left[ \frac{2\Delta(T) C_{\Sigma}}{e^2} + \frac{1}{2} - (-1)^i \left( n + \frac{Q_0}{e} \right) \right]. \]  

(7)

(The last equation is the condition \( W_i^+(n) = 2\Delta(T). \))

At temperatures \( T \) comparable to the critical temperature \( T_c \), the concentration of the thermally excited quasiparticles becomes considerable, and this modifies the shape of the \( I-V \) curve, in particular, creating several additional features at \( V < V_i \). As an example, Fig. 4 shows the theoretical \( I-V \) curve of the symmetrical SET-transistor with \( \Delta(T) = 1.3e^2/C_{\Sigma}, T = 0.4e^2/C_{\Sigma} \) for several values of \( Q_0 \) (relatively large ratio \( \Delta(T)/(e^2/C_{\Sigma}) \) is chosen to show more features). One can see two types of features: peaks (marked by arrows down) and steps (arrows up).

The peaks positions constitute two series

\[ V_{i,n}^{SM} = \frac{e C_i}{C_1 C_2} \left( \frac{1}{2} - (-1)^i (n + \frac{Q_0}{e}) \right), \]  

(8)
which correspond to the condition \( W_i^+(n) = 0 \) (obviously, the condition \( W_i^-(n) = 0 \) gives the same set of voltages). For such tunneling with zero energy gain the singularities of the density of states of two electrodes match (remind that we consider the same \( \Delta(T) \) in all electrodes), that leads to the increase of the tunneling rate \( \Gamma_i^+(n) \) and explains the name of SM peaks. In BCS theory \( \Gamma_i^+(n) \) is formally infinite at \( W_i^+(n) = 0 \) (logarithmic divergence).

Although the current through SET-transistor remains finite being governed by the stationary master equation \( \overline{2} \), the divergence of \( \Gamma \) would lead to very high and narrow center of the SM peak. To take into account the inevitable smoothing of the singularity of \( \rho(\varepsilon) \), in Fig. \( \overline{1} \) we assumed (phenomenologically) a small Gaussian inhomogeneous broadening of \( \Delta(T) \) with dispersion \( w = 0.01\Delta(T) \). The peak height depends very weakly (logarithmically) on \( w \) provided \( w \ll \Delta(T) \).

The origin of SM peaks is similar to that of well-known peaks\( \overline{3} \) on the \( I-V \) curve of a single junction with different energy gaps \( \Delta_1(T) \) and \( \Delta_2(T) \) of electrodes at \( V = [\Delta_1(T) - \Delta_2(T)]/e \). In our case the energy gaps can be the same, and the energy shift is provided by the Coulomb blockade. However, this analogy is not complete. For example, in our case both singularities match simultaneously. Another difference is that the reverse process (tunneling back) also has a large rate, and the net transport is due to the tunneling through the other junction.

The voltage position of SM peaks coincides with the position of the recently observed peaks\( \overline{4} \) in SSS SET at low temperatures when the parity-dependent current is due to the single quasiparticle created by the preceding tunneling event.

At not too high temperatures the SM peaks are more pronounced within the voltage interval \( 2\Delta(T)/e < V < 2\Delta(T)/e + e/C_\Sigma \) (see Fig. \( \overline{4} \)). The lower bound is the condition that the tunneling through the other junction which restores the system into the initial charge state and gives the contribution to the net current, is sufficiently fast, \( W = eV > 2\Delta(T) \).

The upper bound is the condition that after this restoring the tunneling of the next electron through the same junction (which drives the system out of “resonance”) has a small rate, \( W = eV - e^2/C_\Sigma < 2\Delta(T) \). Hence, not more than two closely located peaks from the series given by Eq. (8) can be well pronounced on the \( I-V \) curve.
The important property of SM peaks is their specific temperature dependence. They should be absent at small $T$ (because there are no thermally excited quasiparticles), and their height grows with $T$ for some temperature range (see Fig. 3b below) until they begin to decrease due to the suppression of superconductivity and/or correlation between tunneling events. Notice that the voltage position of SM peaks does not change with temperature despite the dependence $\Delta(T)$.

One can see from Fig. 1 that the SM peaks are rather broad and have asymmetric shape so that they have longer and higher tail at the higher-voltage side. When the peak is not well-pronounced, this tail resembles plateau. When the SM feature is even weaker, it is seen as a small kink on the I-V curve (Fig. 1).

The other features seen in Fig. 1 are the step structures in the $I-V$ curve which are similar to the step at $V = V_t$. Their positions satisfy the same condition $W_i^+(n) = 2\Delta(T)$ and hence, the same Eq. (7) as for $V_t$. So the position of these two series of steps on $V - Q_0$ plane is just a continuation of the straight lines corresponding to $V_t$ (they exist both above and below $V_t$). The steps in Fig. 1 are smoothed because of a finite $w$.

Notice that while the steps corresponding to Eq. (7) are usually positive (increase of the current), they can also be negative – for example, when the step position is on the negative slope of an SM peak (the decrease of the current occurs because the charge state having the resonant tunneling rate becomes less probable).

Besides the steps described by Eq. (7), at relatively high temperatures the theory predicts an appearance of very small negative steps (both below and above $V_t$) at

$$V_{i,n}^{NS} = \frac{eC_i}{C_1C_2} \left[ -\frac{2\Delta(T)C_{\Sigma}}{e^2} + \frac{1}{2} - (-1)^i (n + \frac{Q_0}{e}) \right],$$

that corresponds to the condition $W_i^+(n) = -2\Delta(T)$. The steps are negative because the dependence $\Gamma(W)$ given by Eq. (3) has the step down at $W = -2\Delta(T)$. The effect is very weak because of the factor $\exp(-4\Delta(T)/T)$ and also because of the existence of the opposite effect due to the simultaneous threshold condition $W_i^-(n - (-1)^i) = 2\Delta(T)$ (negative steps have not been observed in our experiment).
The aluminum-based single-electron transistors were fabricated using the standard two-angle evaporation technique. The details of the fabrication are given in Ref. [4]. Figure 2a shows the experimental dependence of the current on the gate voltage for different bias voltages at $T = 650$ mK. The largest feature seen is the Figure is the onset of the fast quasiparticle tunneling at $V > V_t$ (Eq. (6)). (Actually, we see peaks because of the small current scale of the Fig. 2a; for larger bias voltages they transform into plateaus with sufficiently sharp edges.) The well-pronounced peaks along the straight lines intersecting the abscissa axis at $V_g = -14$ mV and $V_g = 32$ mV are JQP peaks (They are due to Josephson coupling and, hence, are outside of the scope of the present paper. The position of JQP peaks is given by Eq. (8) without the term $1/2$ inside parentheses.) The step structures can be seen along the lines (see Eq. (7)) which are the continuation of the main threshold $V_t(V_g)$ (they start from the large features due to $V_t$ in the upper part of Fig. 2a). And finally, the SM peaks are represented as rather broad features along the straight lines approximately in the middle (theoretically exactly in the middle) between JQP lines which intersect the abscissa axis roughly at $V_g \simeq 10$ mV and $V_g \simeq -40$ mV. Small SM peaks have been observed even above $V_t$. The SM features along the line with negative slope are more pronounced than along the line with positive slope possibly because of the difference in junction resistances. Similar measurements made at $T = 50$ mK do not show SM features as well as additional step structures while JQP peaks remain well-pronounced at $V > 0.65$ mV.

Figure 2b shows the numerically determined positions of the maxima of the $I - V_g$ curves from Fig. 2a on $V - V_g$ plane. From the straight lines corresponding to JQP peaks (solid lines) we determine the junction capacitances $C_1 = 183 \pm 4$ aF, $C_2 = 117 \pm 3$ aF. The gate capacitance $C_g = 3.5$ aF which determines the gate voltage period of 46 mV is included into $C_1$ because $V_g$ has been measured from the outer side of $C_1$. Notice that the bias voltage corresponding to the intersection of two JQP lines directly gives the charging energy, $e/C_Σ = 0.53$ mV. The minimal $V_t$ of 0.80 mV is used to determine the superconducting gap $\Delta(T) = 0.20$ meV (minimal $V_t$ corresponds to the edge of the almost vertical curved lines in the upper part of Fig. 2b).
Dashed lines in Fig. 2b show the theoretical position $V_{SM}^{i,n}$ of SM peaks calculated from Eq. (8). We see that experimental peaks are located at somewhat higher bias voltages. This can be explained by several reasons. First, SM feature has a rather smooth shape, and, hence, the addition of any current component which increases with bias voltage leads to the apparent shift of the maximum to higher voltages (we also checked numerically that relatively large inhomogeneous broadening of $\Delta(T)$ leads to a similar shift). Second, the additional contribution to the position shift in Fig. 2b can occur because the peaks are determined as the maximum current point over $V_g$, not over $V$. (The $V_g$ change which decreases $V_{SM}^{i,n}$ also weakens Coulomb blockade in the same junction, hence, increasing the “background” current and leading to the apparent shift of the maximum position.) Finally, the third possible explanation of the shift (which we believe is most likely) is due to the difference between $\Delta(T)$ in the island and leads. Then each SM peak should split in two (there is some experimental evidence of such a splitting which is slightly seen in Fig. 2a and Fig. 3a). Numerical simulations show that the peak corresponding to higher bias voltage is more pronounced (see Fig. 3b) while the lower peak is possibly too small to be represented in Fig. 2b. The difference about 0.02 meV between the energy gaps would be sufficient to explain the experimental deviation.

The experimental temperature dependence of SM peaks on $I - V_g$ curves is shown in Fig. 3a. Besides two SM peaks per period of $V_g$ one can see two steps and two JQP peaks (the heights of JQP peaks are different because the Josephson coupling in one junction has been suppressed). We see that SM peaks as well as steps grow with temperature. Solid lines in Fig. 3b show the corresponding theoretical $I - Q_0$ curves calculated without fitting parameters (JQP peaks are not included in the model). The total resistance $R_{\Sigma} = 605$ kΩ is obtained from the $I - V$ curve and $R_1/R_2 = C_2/C_1$ is assumed. The gap $\Delta(0) = 0.207$ meV is used to get $\Delta(T) = 0.2$ mV at $T = 650$ mK. The small broadening $w = 0.03\Delta(0)$ of the gap was used to eliminate the unphysical divergence of $\Gamma$ at the peak center, while we did not attempt to fit experimental SM peak height by $w$ (larger $w$ decreases the height, though the dependence is quite weak for $w \lesssim 0.05\Delta(T)$). The good correspondence between
Figs. 3a and 3b is an additional proof that the observed peaks are really SM peaks. The dashed curve (corresponding to the top solid curve) illustrates the peak splitting due to different $\Delta(T)$ in the island and leads (difference of 20 meV is used). One can see that this assumption not only explains the peak position shift and traces of such a splitting in experiment, but also improves the agreement for the peak height.

Let us mention that the height of thermally activated JQP peak (at $V < 2\Delta/e + e/2C_\Sigma$) as a function of $V$ ($V_g$ is varied correspondingly) should also exhibit the SM feature at $V = e/2C_\Sigma$ because at this voltage the tunneling of the second quasiparticle in JQP cycle is at resonance. There are some traces of such an increase in Fig. 2a and also one can see qualitatively that in Fig. 2a the JQP peaks start to decrease crudely at $V < e/2C_\Sigma$ (because of the thermal broadening of SM feature this smooth boundary moves to lower voltages by $\delta V \simeq TC_\Sigma/C_i \simeq 0.1$ mV). Similar behavior should be expected for the height of thermally activated steps with SM feature at $V = 2\Delta(T)$.

In conclusion, we observed SM peaks on $I - V_g$ dependence of SSS SET at temperatures comparable to $T_c$. The shape and position of the features agree well with the theoretical prediction.

We thank the group from the University of Jyväskylä for the information about their experimental results prior to publication. The work was partially performed under the management of FED as a part of the MITI R&D Program Superconducting Electron Devices Project supported by NEDO.
