Ocean acidification (OA), which is caused by increasing levels of dissolved CO₂ in the ocean, is a major threat to marine ecosystems. Multiple lines of scientific evidence show that marine bivalves, including scallops, are vulnerable to OA due to their poor capacities to regulate extracellular ions and acid-based status. However, the physiological mechanisms of scallops responding to OA are not well understood. In this study, we evaluated the effects of 45 days of exposure to OA (pH 7.5) on the energy metabolism and antioxidant capability of Yesso scallops. Some biochemical markers related to energy metabolism (e.g., content of glycogen and ATP, activity of ATPase, lactate dehydrogenase, glutamate oxaloacetate transaminase, and glutamate-pyruvate transaminase), antioxidant capacity (e.g., reactive oxygen species level, activity of superoxide dismutase, and catalase) and cellular damage (e.g., lipid peroxidation level) were measured. Our results demonstrate that the effects of the reduced pH (7.5) on scallops are varied in different tissues. The energy reserves are mainly accumulated in the adductor muscle and hepatopancreas. Yesso scallops exhibit energy modulation by increasing lactate dehydrogenase activities to stimulate anaerobic metabolism. The highly active Na⁺/K⁺-ATPase and massive ATP consumption in the mantle and gill indicate that a large amount of energy was allocated for the ion regulation process to maintain the acid-base balance in the reduced-pH environment. Moreover, the increase in the reactive oxygen species level and the superoxide dismutase and catalase activities in the gill and adductor muscle, indicate that oxidative stress was induced after long-term exposure to the reduced-pH environment. Our findings indicate that the effects of OA are tissue-specific, and physiological homeostasis could be modulated through different mechanisms for Yesso scallops.

Keywords: ocean acidification, energy metabolism, oxidative stress, physiological response, scallop

INTRODUCTION

Increasing amounts of anthropogenic CO₂ from the atmosphere dissolved in seawater has changed the overall seawater chemistry with a net increase in hydrogen (H⁺) and bicarbonate ions (HCO₃⁻) and a decrease in carbonate ions (CO₃²⁻), which has already resulted in a 0.1 unit decline in seawater pH since the Industrial Revolution (Caldeira and Wickett, 2003, 2005; Sabine et al., 2004;
Feely, 2011; Perez et al., 2018). These changes are known as ocean acidification (OA). According to the prediction of the Intergovernmental Panel on Climate Change (IPCC), the pH of surface seawater could further decrease to 7.8 and 7.4 by the years 2100 and 2300, respectively (Caldeira and Wickett, 2003; Stocker, 2013). Many studies have confirmed that the predicted changes of seawater pH will have widespread negative effects on the structure, function and fitness of marine ecosystems (Feely, 2011; Uthicke et al., 2013). The variety of responses within and between taxa suggest that OA is a driver for substantial change in ocean ecosystems this century, potentially leading to long-term shifts in species composition (Pörtner and Farrell, 2008; Wittmann and Pörtner, 2013). As a result, understanding the potentials of maintaining physiological homeostasis will help predict biological stability and changes to rapid anthropogenic modifications of ecosystems and ecosystems (Somero, 2010; Applebaum et al., 2014).

Marine bivalves, such as oyster, mussel, clam and scallop, are widely distributed, and they are economically and ecologically important (Gazeau et al., 2013; Kroeker et al., 2013). Scientific literature has revealed that most mollusk species are vulnerable to OA (Pörtner and Farrell, 2008; Wittmann and Pörtner, 2013). To regulate physiological homeostasis, energy is required in response to the environmental changes. Metabolic energy demands under acidification stress may exceed the energy supply from food or/and accrued energy resources, which might lead to a lack of adenosine triphosphate (ATP) to sustain routine metabolism (Lannig et al., 2010). However, some mollusks, such as bivalve fingernail clam Sphaerium occidentale and the cephalopod Nautilus pompilius, can overwhelm the capacity of systemic functions or inhibit the metabolic rate to conserve energy and to extend the survival time (Guppy, 1999). Recent studies have shown that modest increases in dissolved CO$_2$ (<1200 µatm) have little effect on metabolic rates, whereas extremely high levels of dissolved CO$_2$ (>5000 µatm) could depress metabolic rates (Michaelidis et al., 2005; Beniash et al., 2010; Hendriks et al., 2010; Thomsen and Melzner, 2010; Zhao et al., 2017b). As shown by Cao et al. (2018), Pacific oyster (Crassostrea gigas) modulates energy sources by inhibiting aerobic energy metabolism, stimulating anaerobic metabolism, and increasing glycolytic enzyme activity following exposure to a reduced pH value of 7.6 for 28 days. The clams (Ruditapes philippinarum) were reported to be able to maintain/regulate their physiological status and biochemical performance under reduced pH (7.3) for 28 days (Velez et al., 2016). However, in blue mussel Mytilus edulis, energy and protein metabolism were strongly affected by elevated pCO$_2$ (1,120, 2,400, or 4,000 µatm after 2 months of treatment) (Hüning et al., 2013). In addition, some recent transcriptomic analyses have indicated that marine bivalves implement a compensatory acid-base mechanism, metabolic depression and positive physiological responses to mitigate the effects of OA (Goncalves et al., 2016, 2017a,b; Li et al., 2016a,b; Peng et al., 2017).

Oxidative stress, the production and accumulation of reactive oxygen species (ROS), is an important component of the stress response for marine organism when exposed to environmental change (Lesser, 2006). In response to oxidative stress, a wide set of antioxidant systems including superoxide dismutase (SOD) and catalase (CAT) have evolved in marine organisms (Lesser, 2006). The oxidative stress response is prevalent in marine bivalves when exposed to elevated CO$_2$ levels. As shown in the mussel M. galloprovincialis, the oxidative status was negatively affected by reduced pH with an increase in antioxidant enzymes activity and ROS overproduction (Freitas et al., 2017). In the mussel M. coruscus, most biochemical indexes [SOD, CAT, glutathione peroxidase (GPx), acid phosphatase (ACP), and alkaline phosphatase (ALP)] measured in gills and hemocytes were increased when the mussels were subjected to reduced pH (Huang et al., 2018). Nevertheless, no persistent oxidative stress signal was observed during long-term (8ñ15 weeks) exposure to moderately elevated CO$_2$ (~800 ppm CO$_2$) in hard shell clam Mercenaria mercenaria and eastern oyster C. virginica (Matoo et al., 2013). In addition, some studies have demonstrated that the key target genes associated with antioxidant defenses (ecSOD, catalase, and peroxiredoxin 6) were susceptible to OA in marine bivalves (Goncalves et al., 2016, 2017a,b; Li et al., 2016a,b; Wang et al., 2016).

All of these studies indicated that the metabolic effects and antioxidant responses varied among different marine species under elevated dissolved CO$_2$ seawater (Dupont et al., 2010; Hendriks et al., 2010; Kroeker et al., 2010). However, there was very limited information about the effects of OA on scallops (Benedetti et al., 2016; Haider et al., 2016; Nardi et al., 2018). The Yesso scallop (Patinopecten yessoensis) is an economically important shellfish in China, and the production is approximately 240,000 tons in 2016 (data from 2017 China Fisheries Statistical Yearbook). The present study aimed to systematically assess the metabolic effects and antioxidant responses of Yesso scallops under present and future predicted sea surface pH. After 45 days of exposure to two pH levels (8.0 and 7.5), we measured some biochemical markers to determine the energy metabolism levels [assessed by the activity of ATPase, lactate dehydrogenase (LDH), glutamate oxaloacetate transaminase (GOT) and glutamate-pyruvate transaminase (GPT), content of glycogen (GLY) and ATP]; antioxidant capacity (ROS, CAT, and SOD); and cellular damage [measured by the lipid peroxidation (LPO) level] of four tissues (adductor muscle, mantle, gill, and hepatopancreas). The findings of the current study can improve our understanding of the physiological mechanisms involved in regulating energy metabolism and antioxidant responses in marine bivalves when exposed to elevated CO$_2$ levels.

**MATERIALS AND METHODS**

**Experimental Animals Collection and Acclimation**

Samples of 2-year-old Yesso scallops were collected from Haiyi Seeds Co., LTD, in Shandong province, China, in September 2017. The scallops without shell damage were transported on ice to the laboratory and acclimated for 1 week in a recirculated aquarium system equipped with a filtering system (pH 8.0, temperature 18$^\circ$C, and salinity 30.2‰). During the acclimation period, all
scallops were fed twice daily with *Nitzschia closterium* (40,000 cells/animal), and the seawater was changed daily.

**Ocean Acidification Stimulation and Seawater Chemistry Analysis**

After 1 week of acclimation, the healthy scallops were randomly divided into two groups and placed in two different environments: the control group at a pH of 8.0 (current concentration of pCO$_2$) and the experimental group at a pH of 7.5 (representing the predicted water surface pH level of the twenty-first century) (Caldeira and Wickett, 2003; Stocker, 2013). For each treatment, there were three replicates of ~50-L tanks, holding ten scallops each. The reduced pH value (pH 7.5) was maintained by vigorously bubbling ambient air or a CO$_2$ gas mixture. The CO$_2$ gas mixture was obtained by mixing CO$_2$-free air and pure CO$_2$ gas at known flow rates using flow controllers (Zhao et al., 2017a). The pH of seawater was monitored using a pH meter (Sartorius PB-10) to ensure no substantial change in pH during the experiment. The other seawater parameters including salinity, temperature and dissolved oxygen (DO) were measured daily by a multi-parameter water quality meter (HORIBA U-52, Japan). The total alkalinity (TA) was monitored once a week by potentiometric titration (Anderson and Robinson, 1946). The carbonate system parameters were calculated using CO2SYS software (Pierrot et al., 2006), and the seawater parameters for the experimental exposures are given in Table 1.

**Biochemical Assays**

After 45 days of experiments, six scallops per treatment were collected at random. Four tissues, including the adductor muscle, mantle, gill and hepatopancreas were collected from each scallop. After 45 days of experiments, six scallops per treatment were collected at random. Four tissues, including the adductor muscle, mantle, gill and hepatopancreas were collected from each scallop. After 45 days of experiments, six scallops per treatment were

The pH$_{NBS}$, pH calibrated with National Bureau of Standard scale; T, temperature; Sal, salinity; TA, total alkalinity; pCO$_2$, partial pressure of CO$_2$; Ωc and Ωa, saturation state of calcite and aragonite, respectively. Data are presented as the means ± standard deviations.
The LDH activity was measured by the trace enzyme labeling method (Weeks and Johnson, 1977), which is based on the function of LDH in catalyzing the formation of pyruvate. The pyruvate was reacted with 2, 4-dinitrophenylhydrazine in a terminal indicator reaction to form the characteristic brown color of the corresponding 2, 4-dinitrophenylhydrazone pyruvate, which was measured colorimetrically at 440 nm. One unit of LDH activity was defined as the formation of 1 µmol pyruvate per 15 min per gram protein.

The ATP content was determined according to the phosphomolybdic acid colorimetry method (Chen and Sun, 2002). It is an indirect method for determining the ATP level. In brief, creatine kinase was added to catalyze the formation of ADP and inorganic phosphorus. The activity of ATPase was judged by the amount of inorganic phosphorus, which was interacted with a phosphorus-fixing agent for 30 min at 37°C. The absorbance was measured at 660 nm when the product cooled to room temperature, and one unit of ATPase was defined as the product of 1 µmol inorganic phosphorus per hour per milligram of protein.

The ATPase activity was quantified following the protocol of the ATP enzyme test kit (Na\(^+\)/K\(^+\)-ATPase and Ca\(^{2+}\)/Mg\(^{2+}\)-ATPase) from Nanjing Jiancheng Bioengineering Institute, which was based on ATPase function in decomposing ATP to produce ADP and inorganic phosphorus. The activity of ATPase was judged by the amount of inorganic phosphorus, which was interacted with a phosphorus-fixing agent for 30 min at 37°C. The absorbance was measured at 660 nm when the product cooled to room temperature, and one unit of ATPase was defined as the product of 1 µmol inorganic phosphorus per hour per milligram of protein.

The GPX and GOT activities were quantified following the method of Reitman and Frankel (1957). The activity of GPX or GOT was measured by mixing tissue suspension with the corresponding substrate. Both enzymes were act on catalyzing the transamination of substrate and the formation of pyruvate. After a 30-min interaction at 37°C, 2, 4-dinitrophenylhydrazine solution was added to stop the transamination and reacted with pyruvate for 20 min at 37°C. Subsequently, the reaction liquid was mixed with NaOH solution for 15 min at room temperature. The optical density was read at 505 nm. The results were referred to the standard curve drawn by the pyruvate standard solution with gradient concentrations and expressed in unit per gram of protein.

**Statistical Analysis**

The statistical analyses of the data were preformed using SPSS software (version 20.0). The data collected from this study are expressed as the means ± standard deviation (N = 6). A one-way analysis of variance (ANOVA) and Tukey’s test were used to differentiate between the means. Tests were considered significant at p < 0.05.

**RESULTS**

The levels of ROS, LPO, SOD and CAT in the adductor muscles, mantles, gills and hepatopancreas of scallops exposed to reduced-pH seawater and ordinary seawater (control) are illustrated in Figure 1. The levels of ROS in all tested organs were generally higher in the scallops exposed to reduced-pH seawater compared with the control group. The results of the statistical analyses demonstrate that the ROS levels in the gills and hepatopancreas were significantly higher (p < 0.05) in the scallops exposed to reduced-pH seawater than in the control group.

For the LPO levels, no significant difference (p > 0.05) was observed in all organs between the scallops exposed to reduced-pH seawater and the control group. The SOD activities in the adductor muscles and hepatopancreas were significantly higher (p < 0.05) in the scallops exposed to reduced-pH seawater than in the control group. However, the SOD activities in the gills was significantly lower (p < 0.05) in the scallops exposed to reduced-pH seawater (6.19 ± 0.46 U mgprot\(^{-1}\)) than in the control group (130.06 ± 33.73 U mgprot\(^{-1}\)). For the CAT activities, the scallops exposed to reduced-pH seawater demonstrated significantly higher (p < 0.05) CAT activity in the adductor muscles (99.96 ± 36.95 U mgprot\(^{-1}\)) compared with the scallops in the control group (14.58 ± 2.80 U mgprot\(^{-1}\)).

The effects of reduced pH on different types of ATPase were varied in the four tissues (Figures 2A, B). The activities of Na\(^+\)/K\(^+\)-ATPase in the mantles and gills of the scallops exposed to reduced-pH seawater were significantly higher (p < 0.05) than in the respective organs of the scallops in the control group. The Ca\(^{2+}\)/Mg\(^{2+}\)-ATPase activity in the gills of the scallops exposed to reduced-pH seawater (5.13 ± 0.39 µmolPi mgprot\(^{-1}\) h\(^{-1}\)) were significantly lower (p < 0.05) than in the gills of the scallops in the control group (7.98 ± 0.42 µmolPi mgprot\(^{-1}\) h\(^{-1}\)). For ATP contents, the scallops exposed to reduced-pH seawater demonstrated significantly lower (p < 0.05) ATP contents in the mantles (168.13 ± 52.79 µmol gprot\(^{-1}\)) compared with the scallops in the control group (483.86 ± 91.41 µmol gprot\(^{-1}\)) (Figure 2C).

The results of the statistical analyses demonstrated that the GLY content in the adductor muscles was significantly lower (p < 0.05) in the scallops exposed to reduced-pH seawater (2.06 ± 0.52 mg g\(^{-1}\)) compared with the control group (4.32 ± 0.53 mg g\(^{-1}\)). However, the GLY content in the hepatopancreas was significantly higher (p < 0.05) in the scallops exposed to reduced-pH seawater (5.70 ± 0.38 mg g\(^{-1}\)) compared with the control group (4.58 ± 0.09 mg g\(^{-1}\)) (Figure 3A). The LDH activities in the adductor muscles of the scallops exposed to reduced-pH seawater (1565.31 ± 0.01 U gprot\(^{-1}\)) were significantly higher (p < 0.05) than in the adductor muscles of the scallops in the control group (861.53 ± 134.71 U gprot\(^{-1}\)) (Figure 3B).

For the GOT and GPT activities, no significant difference (p > 0.05) was observed in the adductor muscles, mantles and gills between the scallops exposed to reduced-pH seawater and the control group. However, the GPT activity in the hepatopancreas was significantly lower (p < 0.05) in the scallops exposed to reduced-pH seawater (5227.44 ± 817.48 U gprot\(^{-1}\)) compared with the control group (8294.14 ± 628.25 U gprot\(^{-1}\)) (Figure 4).

**DISCUSSION**

Ocean acidification caused by increased CO\(_2\) emission to the atmosphere has been showed in all areas of the ocean including

deep sea and coastal waters (Orr et al., 2005; Wittmann and Pörtner, 2013). The impacts of OA are more substantial in coastal waters, where the ecosystem responses to OA could have the most severe implications for mankind (Doney et al., 2007; Feely et al., 2008, 2009, 2010; Wootton et al., 2008; Zhai et al., 2012). Coastal organisms show diverse responses to elevated seawater pCO$_2$ (Pörtner and Farrell, 2008; Ries et al., 2009; Hendriks et al., 2010; Wittmann and Pörtner, 2013). The Yesso scallop is an economically important marine shellfish. This species has long been cultivated in the coastal ocean of China, Japan, and Russia (Shumway and Parsons, 2006). However, the potential effects of OA on the physiology of Yesso scallop is still unknown. Thus, the current study aims to evaluate the effects of OA on the scallop based on physiological and biochemical markers.

As a major form of energy storage in cells, GLY supplies energy quickly through glycolysis and oxidative phosphorylation. Adequate glycogen storage in muscle is important to support the optimal movement of muscle (Jensen and Richter, 2012). In the current study, low pH stress resulted in a decrease in glycogen level but an increase in LDH activity in the adductor muscles of scallops. A similar observation has been reported in $C$. gigas, where the GLY level in muscle tissue decreased after exposure to low pH seawater (Lannig et al., 2010). On the other hand, under stressful environments, LDH is an important enzyme that accelerates ATP production through anaerobic processes to maintain energy homeostasis (Strahl et al., 2011). The combined effects of elevated LDH activity and decreased GLY level in muscle tissues suggest that OA accelerates glycolysis, which might be an energy strategy of the Yesso scallop to fuel the high energy demand. The hepatopancreas is another important energy storage organ, and it plays an important role in energy homeostasis of the blood circulation system (Barber and Blake, 1985). The rising in GLY content in the hepatopancreas of the Yesso scallop during reduced-pH exposure suggests that some of the lactic acids from the muscle tissues entered the hepatopancreas through the blood circulation system, where they were then resynthesized to GLY for energetic conservation.

The transaminase GPT plays a key role in mobilizing L-amino acids for gluconeogenesis, and it acts as a link between carbohydrate and protein metabolism under altered physiological, pathological, and induced environmental stress conditions (Ramaswamy et al., 2015). However, the influences of acidification on GPT activity varies by species. A study on the thick shell mussel $M$. coruscus found that the activity of GPT in the gill and digestive gland increased when exposed to reduced-pH seawater (Hu et al., 2015). The current study recorded a contradictory result, where the GPT activity decreased in $P$. yessoensis under the reduced-pH treatment. The hepatopancreas is a major organ for gluconeogenesis. The
The enzyme Na\(^+\)/K\(^+\)-ATPase is the main motor of cellular and extracellular acid-base balance and thus acts as an important ion regulatory player, and it may be related to the capability of each species to acclimate to pH fluctuations (Melzner et al., 2009; Velez et al., 2016). The highly active Na\(^+\)/K\(^+\)-ATPase and massive consumption of ATP in the mantle of P. yessoensis suggest that a large amount of energy in the mantle was allocated to the ion regulation process to maintain the acid-base balance in the reduced-pH environment. In the mantle of the oyster C. gigas following OA-exposure (pH ∼ 7.7) for 1 month, both the ATP content and alanine levels decreased, but the Na\(^+\)/K\(^+\)-ATPase activities were not affected. The authors suggested that alanine is transaminated to pyruvate, which together with ATP is used to build up phosphoenolpyruvate (PEP), with PEP as the substrate entering the gluconeogenetic pathway (Lannig et al., 2010). Other than the mantle, the Na\(^+\)/K\(^+\)-ATPase activities in the gill of P. yessoensis were also elevated after OA exposure. On the other hand, the reduced-pH treatment decreased the Ca\(^2+\)/Mg\(^{2+}\)-ATPase activity without affecting the ATP content in the gills of Yesso scallops. Therefore, it is reasonable to believe that the Yesso scallop could shift the use of its ion regulation mechanism by reducing the Ca\(^2+\)/Mg\(^{2+}\)-ATPase activity and increasing the Na\(^+\)/K\(^+\)-ATPase activity simultaneously to regulate the acid-base balance under low pH exposure. A similar result has been documented in Atlantic cod (Gadus morhua), where a shift in the use of ion regulation mechanisms occurred toward enhanced Na\(^+\)/H\(^+\)-exchange and HCO\(_3\)\(^−\) transport at high PCO\(_2\) (2200 µatm), paralleled by higher Na\(^+\)/K\(^+\)-ATPase activities, which did not affect the total gill energy consumption and left the whole animal energy budget unaffected (Kreiss et al., 2015).

Reactive oxygen species production is an important internal defense mechanism in bivalves such as Mytilus edulis, Cerastoderma edule, and Ensis siliqua (Wootton et al., 2003; Terahara and Takahashi, 2008). When the ROS content exceeds the antioxidant capacity, the excess ROS may lead to cell oxidative damages, such as DNA damage, membrane lipid damage and enzyme inactivation (Cheng et al., 2004a,b). Increasing ROS content and active peroxidase activities after low pH exposure have been reported in M. coruscus, C. ariakensis, and C. gigas (Bouilly et al., 2006; Gagnaire et al., 2006; Donaghy et al., 2009; Wang et al., 2016; Wu et al., 2016). In the current study, exposure to reduced-pH seawater led to high ROS production in the gill and hepatopancreas of P. yessoensis. The gill plays a vital role in respiration, and the hepatopancreas is a major organ for metabolism. These two organs have been shown to be sensitive to environmental stress in bivalves (Farcy et al., 2009; Lockwood et al., 2010). The high ROS content indicates that the oxidative stress occurred in the gill and hepatopancreas of Yesso scallops.

The levels of LPO, SOD, and CAT enzyme activities have been used as biomarkers to assess oxidative stress (Livingstone, 2001; Soldatov et al., 2007; Velez et al., 2016). In our study, the lipid peroxidation level did not change significantly in the reduced-pH group, suggesting that the reduced-pH treatment has little effect on the lipid peroxidation. A similar result was reported in the clam, R. philippinarum (Velez et al., 2016). However, the SOD activities were elevated in the adductor muscles and hepatopancreas but decreased in the gill of P. yessoensis.
after exposure to a reduced-pH seawater. The induction of SOD, a primary scavenger of O$_2^-$ generated during stress condition, could inhibit the accumulation of oxygen radicals during exposure to low pH seawater. The weakening SOD activity in the gill tissue could indicate oxidative stress. Furthermore, the increased SOD activity resulted in a high level of H$_2$O$_2$, which should stimulate CAT activity. In our study, the activity of CAT increased in the adductor muscles, which could have been stimulated by the increased SOD activity.

CONCLUSION

The findings of the present study demonstrate that a reduction in seawater pH to 7.5 can potentially interfere with the energetic metabolism and antioxidant responses of scallops. Alteration of the energy demand or reserve has been observed in Yesso scallops after exposure to a reduced-pH environment. The muscle glycogen was decomposed and the activity of LDH increased, leading to suppressed aerobic metabolism and increased anaerobic metabolism. At the same time, the content of glycogen increased in the hepatopancreas, indicating that scallops were able to reserve some energy when exposed to a reduced-pH environment. In addition, the high Na$^+$/K$^+$.ATPase activities in the mantle and gill suggest that energy was allocated to ion transport in maintaining the intracellular and extracellular acid-base balance. Moreover, increased oxidative stress was also induced after long-term exposure to reduced-pH seawater. Overall, our findings are useful for a better understanding of the biochemical strategies and biological limitations of scallop if the ocean acidification worsens as predicted.
