Introduction

Ectodermal dysplasia syndromes (ED) refer to a group of heterogeneous, inherited disorders characterized by abnormal development of tissues and organs derived from the ectoderm. The incidence is 1 in 100,000 people. There are over a hundred types with variable expression of the effects to the primary and permanent dentitions, skin, sweat glands, hair, nails and other ectodermal structures.\(^1\) The majority of the subjects affected by the condition have normal brain development and life expectancy. The two major types of ED syndromes are described as hypohidrotic and hidrotic, depending on sweat gland function.

Abstract

The purpose of this study was to test two 8-year-old identical twins with ectodermal dysplasia (ED) and their unaffected parents for the presence of mutations in the *EDA* gene with the hypothesis that they might be carrying a *de novo* mutation in EDA and potentially eligible for recombinant EDA therapy. DNA was extracted using saliva samples obtained from the identical twin girls and both parents. PCR products of Ectodysplasin A (*EDA*), Ectodysplasin Receptor (*EDAR*), Ectodysplasin Receptor Associated Death Domain (*EDARADD*), and Connexin-30 (*GJB6*) were sequenced by the Sanger method and the results analyzed using a reference sequence. Exons and exon-intron boundaries of *EDA*, *EDAR*, *EDARADD*, and *GJB6* were sequenced in both parents and the affected identical twin pair. No mutations were detected in *EDA* or *GJB6*. Genetic variants located in the intron of *EDAR* were found but determined to be non-contributory to the twins’ ED. A microsatellite polymorphism was detected in all four subjects in exon 4 of the *EDARADD* gene but determined not to be causal to the ED. There was a silent mutation detected in exon 6 of the *EDARADD* gene of both the daughters and their unaffected mother but also unlikely to be the cause of ED. These results suggest that ED of the subjects is caused by a *de novo* mutation in a gene not studied here. It is likely these subjects and their future offspring would not benefit from the development of recombinant EDA replacement therapy.

**Key words:** Ectodermal dysplasia, EDA, mutation.
Hypohidrotic ED (HED) is the most common form and is named for the absence of sweat glands. Dry skin, eyes, airways and mucous membranes can occur as a result of impaired development of exocrine glands. In addition to the hypohidrosis seen in HED, hypotrichosis and severe hypodontia are usually present.

ED can be inherited by multiple Mendelian pathways: X-linked recessive, autosomal dominant, autosomal recessive, or de novo. Although there are multiple patterns of inheritance, the genetic mutation most commonly occurs in the EDA (Ectodysplasin A) gene complex (Figure 1).

Recombinant EDA replacement therapy was successful in dogs and is a promising approach to correct the consequences of inactivating mutations of ectodysplasin A (EDA) that lead to X-linked ectodermal dysplasia (ED) in humans. Identification of potential subjects for a future human trial is an important component of the planning phase of future studies.

The aim of this research hypothesis was to test two 8-year-old identical twin sisters with ED and their unaffected parents for the presence of mutations in the EDA gene with the hypothesis that they might be carrying a de novo mutation in EDA and potentially eligible for recombinant EDA therapy. A complete understanding of the etiology of their ED would be used in conjunction with clinical and environmental features to make appropriate treatment recommendations.

Case report

Identical 8-year-old twin girls were referred by a private dentist in Johnstown, PA, to the University of Pittsburgh School of Dental Medicine (SDM), Department of Pediatric Dentistry (Figure 2). Detailed extraoral and intraoral clinical presentation features were recorded for the twin patients, their parents and one grandparent. The children were confirmed to have ectodermal dysplasia primarily affecting their teeth. There were no other obvious features of ectodermal dysplasia such as sparse hair, dry skin, dystrophic nails, or reports of lack of sweating or fevers when temperature is high. The unaffected mother had agenesis of three third molars (both maxillary and left mandibular) and no other relevant findings. The father was unaffected with an intact dentition. They have a younger brother. The paternal grandmother had agenesis of the left mandibular lateral incisor and the paternal grandfather had no history of tooth agenesis. No information could be obtained for the maternal grandparents.

The subjects and their parents were part of the University of Pittsburgh School of Dental Medicine Dental Registry and DNA Repository project, which is approved by the University of Pittsburgh Institutional Review Board (University of Pittsburgh IRB approval 0609091). Informed consent was obtained from the parents and appropriate assent was obtained from the patients to provide a saliva sample without the use of saliva stimulatory tools. DNA was isolated from the saliva samples collected from the twin children and their parents in Oragene kits (DNA Genotek, ON, Canada) according to the manufacturer's instructions. Primers for the Ectodysplasin (EDA), Ectodysplasin Receptor (EDAR), Ectodysplasin Receptor Associated Death Domain (EDARADD), and Connexin-30 (GJB6) genes were obtained from the literature. The primers used are listed in Table 1.

Polymerase chain reaction (PCR) conditions were optimized for the primers using stock DNA and a standard PCR protocol. The standard PCR protocol consisted of an initial denaturation step at 95°C for 30 seconds, followed by 30 cycles of denaturation at 94°C for 45 seconds, with a final extension step at 72°C for 5 minutes. PCR product amplification was confirmed by a 3% ethidium bromide agarose gel.

Figure 1. Ectodysplasin-EDAR-EDARADD pathway [modified from (5)].

Figure 2. The studied twin sisters.
PCR products were cleaned using the PEG precipitation of PCR product protocol. The samples were prepared for sequencing by the Sanger sequencing method used at the Genomics and Proteomics Core facility at the University of Pittsburgh. Microsequencing was completed by capillary electrophoresis using either an Applied Biosystems 3130 or 3730 XL DNA analyzer. The Applied Biosystems sequence software was used for lane tracking and first pass base calling. The sequences were analyzed for mutations by comparing the obtained sequence with a reference gene sequence. Sequencing results were also studied in relation to the clinical presentations of the twin patients and their parents.

Exons and introns from *EDA, EDAR, EDARADD* and *GJB6* were sequenced for both parents and the affected daughters. No mutations were detected in *EDA* or *GJB6*. Genetic variants located in the intron of *EDAR* were found but determined to be non-contributory to the twins’ ED. A microsatellite polymorphism was detected in all four subjects in exon 4 of the *EDARADD* gene but determined not to be causal to the ED. There was a silent mutation detected in exon 6 of the *EDARADD* gene of both daughters and their mother. This mutation was not found in the father and was unlikely to be the cause of the ED. The base pair T replaced a C but translated to the same amino acid, aspartic acid. This silent mutation has already been reported in the literature and is unlikely to be responsible for ectodermal dysplasia.

**Discussion**

Based on clinical presentations, as well as the genetic analysis of the twin girls and their parents, an X-linked recessive pattern of inheritance can be ruled out as a mode of inheritance. There were no mutations found in the *EDA* exons commonly associated...
with X-linked recessive inheritance. These data confirm that the inheritance pattern is most likely not X-linked recessive.

There were no mutations found in the EDAR, nor were EDARADD exons reported in conjunction with autosomal dominant and recessive forms of ED. No mutations were detected in EDA or GJB6. These findings cannot confirm an autosomal dominant or recessive transmission either. According to this initial genetic analysis, the ED mutation is probably located on another gene not examined in this family. An autosomal dominant, or recessive, de novo genetic mutation may be located in another pathway involved in ectodermal development in genes such as MSXI or members of the WNT family. It is likely that the ED of these subjects is caused by a de novo mutation in a gene not studied yet. Clinically, the case presented here has the primary features of an ectodermal dysplasia affecting teeth and is comparable to previous reports that identified mutations in EDA, EDAR, EDARADD or GJB6. Aside from the challenges of rehabilitating extensive areas of the arches with congenitally missing teeth, the lifetime prognosis of the condition in the affected children is unlikely to be different from any other similar cases.

Additionally, analysis of these genes and others is necessary to confirm the etiology of ED in the twin's patients. Further research in this area would include sequencing genes outside of the EDA complex less commonly associated with ectodermal dysplasia syndromes. These genes would include MSXI or genes in the WNT pathway.

**Conclusion**

1. Four different genes commonly associated with ED were eliminated as the location of the disease-causing mutation. These results suggest that the ED of the subjects is caused by a de novo mutation in a gene not studied here. Aside from defining the ectodermal dysplasia of these patients as primarily affecting the teeth, we are not able to be more precise.
2. It is likely that these subjects and their future offspring would not benefit from the development of recombinant EDA replacement therapy.
3. When the precise sporadic mutation is confirmed, patients with ED can be provided with a diagnostic target for prenatal management. In confirming the genetic etiology, the patients and their parents may more readily accept the situation in knowing the cause. This acceptance may help them better live with the disorder.
