Abstract. Organic aerosol (OA) emissions from biomass burning have been the subject of intense research in recent years, involving a combination of field campaigns and laboratory studies. These efforts have aimed at improving our limited understanding of the diverse processes and pathways involved in the atmospheric processing and evolution of OA properties, culminating in their accurate parameterizations in climate and chemical transport models. To bring closure between laboratory and field studies, wildfire plumes in the western United States were sampled and characterized for their chemical and optical properties during the ground-based segment of the 2019 Fire Influence on Regional to Global Environments and Air Quality (FIREX-AQ) field campaign. Using a custom-developed multiwavelength integrated photoacoustic-nephelometer (MIPN) spectrometer in conjunction with a suite of instruments, including an oxidation flow reactor equipped to generate hydroxyl (OH∙) or nitrate (NO₃∙) radicals to mimic daytime or nighttime oxidative aging processes, we investigated the effects of multiple equivalent days or nights of OH∙/NO₃∙ exposure on the chemical composition and mass absorption cross-sections (MAC(λ)) at 488 and 561 nm of OA emitted from wildfires in Arizona and Oregon. We found that OH∙ exposure induced a slight initial increase in absorption corresponding to short timescales, however, in longer time scales, the wavelength-dependent MAC(λ) decreased by a factor of 0.72 ± 0.08, consistent with previous laboratory studies and reports of photobleaching. On the other hand, NO₃∙ exposure increased MAC(λ) by a factor of up to 1.69 ± 0.38. We also noted some sensitivity of aerosol aging to changing different fire conditions between Arizona and Oregon. The MAC(λ) enhancement following NO₃∙ exposure was found to correlate with an enhancement in CHO₁N and CHO₁/N ion families measured parallelly using the Aerodyne aerosol mass spectrometer.

We found that OH∙ exposure initially slightly increased absorption, and subsequently, reduced the wavelength-dependent MAC(λ) by a factor of 0.72 ± 0.08, consistent with previous laboratory studies and reports of photobleaching. On the other hand, NO₃∙ exposure increased it by a factor of up to 1.69 ± 0.38, though the absorption increase due to aging was found to have some relationship to fire conditions. The MAC enhancement...
1 Introduction

Wildfires constitute one of the main contributions to the global atmospheric organic aerosol (OA) burden (Murphy et al., 2006; Zhang et al., 2007). The diverse physical, chemical, and optical properties of OA, the varied pathways involved in their formation in fires, and subsequent atmospheric processing introduce uncertainty into the analysis of their climate impacts, preventing extensive and accurate representation within regional and global scale models. Laboratory studies have, in the recent several years, demonstrated the effects of atmospheric processing on the optical, chemical, and physical properties of biomass burning OA (BBOA) or secondary organic aerosol (SOA) from biomass sources (Jimenez et al., 2009; Kroll et al., 2011; Lambe et al., 2013; Sumlin et al., 2017a). BBOA is typically also associated with brown carbon (BrC), a class of OA known to strongly absorb sunlight in the UV and short visible wavelengths (Pósfai et al., 2004; Chakrabarty et al., 2010). Following diurnal cycles, the impacts of atmospheric oxidation can be broadly divided into daytime- and nighttime-driven processes. During daylight hours, the dominant oxidant that may influence OA properties is OH. At night, when OH production is significantly lower, O₃ or NO₃ are the most likely oxidants to influence biomass burning OA (BBOA) properties. Initial laboratory studies suggest OH- and NO₃-induced oxidative aging affect the light absorption properties of BBOA surrogates in markedly different ways. OH exposure to diminish light absorption by fragmenting large chromophoric molecules (Lambe et al., 2013; Sumlin et al., 2017a), while NO₃ oxidation has been shown to enhance light absorption by adding nitrogen-containing chromophoric functional groups (Li et al., 2019; Cheng et al., 2020; Li et al., 2020; He et al., 2021).

The need to study the consequences of such atmospheric processing on BBOA has motivated the development and use of environmental chambers capable of containing and controlling a sample of aerosol as it ages naturally (such as a Teflon bag sitting in open sunlight) or by accelerating the aging process by exposing aerosols to increased concentrations of atmospheric oxidants, UV light, or both (Carter et al., 1995; Cocker et al., 2001; Grieshop et al., 2009; Cubison et al., 2011; Ortega et al., 2013). Such chambers are often large, on the order of several cubic meters (Cocker et al., 2001), and the relatively slow pace of a given experiment may suffer from unrealistic loss mechanisms including wall losses (including electrostatic, diffusional, and gravitational) (McMurry and Grosjean, 1985; Zhang et al., 2014; Wang et al., 2018) and aerosol agglomeration and coagulation (Pierce et al., 2008). Recently, oxidation flow reactors (OFRs) have been used as a field-deployable alternative to traditional environmental chambers. OFRs are comparatively small, on the order of 0.01 m³, with residence times on the order of minutes and oxidant concentrations that are 100-1000 times higher than typical ambient levels, resulting in equivalent atmospheric aging time scales from hours to weeks (Lambe et al., 2011).

While most work with OFRs has focused on OH-initiated oxidative aging processes, new methods are available to employ NO₃ in field-based OFR studies (Lambe et al., 2020; Li et al., 2020) that expand on previous work (Palm et al., 2017). The consequences of such atmospheric processing over multiple diurnal cycles and broad geographical areas introduce significant errors into the aerosol components of radiative transfer models and make it difficult to constrain the impacts that wildfires and other large-scale aerosol events will have on the climate, especially in areas where air quality is expected to suffer under the effects of anthropogenic climate change (McClure and Jaffe, 2018). Following previous laboratory studies that investigated the various properties of BrC generated from smoldering
biodiversity (Sumlin et al., 2017b; Sumlin et al., 2018a; Sumlin et al., 2018b), including their optical characteristics following OH∙ exposure in an OFR, this work investigates the effects of daytime and nighttime aging on the short visible wavelength-dependent light absorbing properties of smoke OA sampled during the Fire Influence on Regional to Global Environments and Air Quality (FIREX-AQ) campaign, an interagency mission led by NASA and NOAA, conducted during the wildfire season of 2019 (Warneke, in preparation). This work focuses on four OFR-based OA oxidative aging experiments performed in August 2019 at ground level near the North Rim of the Grand Canyon in Arizona during the Castle and Ikes fires, and in Eastern Oregon, during the 204 Cow Fire. Results are used to quantify the effects of diurnal cycle driven oxidation processes on the OA mass absorption cross-section.

2 Methods

2.1 Wildfire emissions sampled during OFR experiments

2.1.1 Castle and Ikes Fires, Northern Arizona

At the time of the FIREX-AQ campaign, two large fires were burning in close proximity to each other near the North Rim of the Grand Canyon, near Page, AZ. These fires, the Castle and Ikes fires (36.51° N, 112.28° W, and 36.35° N, 112.29° W, respectively), were ignited by lightning on 12 and 25 July 2019, respectively, by lightning strikes. Since these fires threatened no structures or other property and were burning through a forest densely packed with litter, underbrush, and dead fallen trees, the fires were allowed to burn within prescribed limits to serve their role as the forest’s natural mechanism of cleanout and renewal while fire crews in the area used Castle and Ikes as training opportunities.

The Castle and Ikes fires burned near the Oquer Canyon in the Kaibab National Forest, a densely forested area consisting predominantly of Ponderosa pine (Pinus ponderosa), Douglas fir (Pseudotsuga menziesii), Engleman spruce (Picea engelmannii), and quaking aspen (Populus tremuloides). Minor species include Gambel oak (Quercus gambelii), and various shrub and grass species of sagebrush (Artemesia) and bitterbrush (Purshia). A complete description of the fuel bed in this region are given in Appendix A of Riccardi et al. (2007). By 20 August 2019, the fire management areas had grown to approximately 24,000 acres (~97 km²) combined. The Aerodyne Mobile Laboratory (AML, described below) approached from Page via Highway 89A and State Route 67. An OH∙-OFR experiment (OH∙Arizona) was conducted on 20 August at approximately 17:45 UTC (10:45 MST) at 36.61°N, 112.19°W (Fig. 1), and a NO3∙-OFR experiment (NO3∙Arizona) was conducted on 22 August at approximately 10:30 UTC (03:30 MST) at 36.54° N, 112.17° W (Fig. 2).

[Figure 1]

[Figure 2]
2.1.2 204 Cow Fire, Eastern Oregon

After returning from Arizona, the nearest fire of interest was the 204 Cow Fire (44.28° N, 118.47° W) in the Malheur National Forest region of the Blue Mountains in eastern Oregon, approximately 200 km west-southwest of McCall. The 204 Cow Fire was ignited on 9 August by lightning and grew to burn 9,668 acres (approximately 29 km²) until its containment on 15 October. The region is predominantly forested by various species of pine, fir, and juniper trees (Pinus, Abies, and Juniperus, respectively) along with shrub species of sagebrush (Artemesia) (Riccardi et al. 2007). The fire had burned approximately 5,500 acres (22.3 km²) by 26 August, when both OH-OFR (“OHOregon”, 09:30 UTC, 03:30 MDT, 44.23° N, 118.40° W) and NO3-OFR (“NO3Oregon”, 12:30 UTC, 06:30 MDT, 44.25° N, 118.40° W) experiments took place (Fig. 3). The AML approached from State Route 26 and then traversed a series of National Forest Development roads to conduct sampling less than 3 km from the fire management area.

[Figure 3]

2.2 Instrumentation

2.2.1 Multiwavelength Integrated Photoacoustic-Nephelometer (MIPN)

A description of the design and development of this instrument, including calibration procedures, has been given previously (Arnott et al., 1999; Arnott et al., 2000; Moosmüller and Arnott, 2003; Varma et al., 2003; Lewis et al., 2008). Briefly, the aerosol light absorption coefficient (βabs, Mm⁻¹) was measured with the prototype version of a new Multiwavelength Integrated Photoacoustic-Nephelometer (MIPN) at two wavelengths (λ = 488 and 532 nm). The MIPN is based upon single-wavelength instruments constructed at Washington University in St. Louis and described previously (Sumlin et al., 2017a; Sumlin et al., 2018a; Sumlin et al., 2018b). Novel to the MIPN is a dual-cell arrangement wherein the sample stream is split and one branch is filtered to remove particulate matter, thereby simultaneously sampling a particle-free gaseous background to account for noise from various sources such as ambient acoustic, electrical, and flow noise. Data were acquired from each wavelength in serial at 0.5 Hz for one minute per
wavelength and averaged across each wavelength’s one-minute cycle. Due to a field malfunction, scattering measurements were not obtained. OA mass absorption cross-sections (MAC(\(\lambda\)), m² g⁻¹) at the two operating wavelengths were calculated from the ratio of \(\beta_{\text{abs}}\) measured with MPIN and OA mass concentrations measured with the SP-AMS after correcting for dilution and wall losses in the OFR. We additionally calculated the MAC(\(\lambda\)) enhancement, \(E_{\text{MAC}}(\lambda)\), from the ratio of OFR-processed and ambient MAC(\(\lambda\)) values. Thus, \(E_{\text{MAC}}(\lambda) > 1\) indicates an oxidative aging-induced absorption enhancement, while \(E_{\text{MAC}}(\lambda) < 1\) indicates diminished absorption enhancement. To obtain reasonable estimates for \(E_{\text{MAC}}(\lambda)\) values that are comprehensive of a given oxidation step yet still capture the nature of the dynamic plume, \(E_{\text{MAC}}(\lambda)\) was calculated using the average of aerosol MAC(\(\lambda\)) during a given oxidation step divided by the average of the ambient steps immediately prior and after.

2.2.2 Aerosol Mass Spectrometer
The SP-AMS is a standard Aerodyne high resolution time of flight aerosol mass spectrometer (HR-ToF-AMS) with an intracavity, CW laser vaporizer (Onasch et al., 2012). The AMS was operated to provide online chemically-speciated mass and sizing measurements of both non-refractory and refractory particles between approximately 70 – 2500 nm in aerodynamic diameter. A PM2.5 inlet lens was installed on the AMS for this study, extending the range of 100% transmission efficiency of particles through the lens up to 2.5 \(\mu\)m in diameter. The SP-AMS laser was operated with approximately a 50% duty cycle. When the laser was off, the system was operated as a conventional AMS. During OH\(_{\text{Arizona}}\), OH\(_{\text{Oregon}}\), and NO\(_3\)\(_{\text{Oregon}}\), the SP-AMS was used. During NO\(_3\)\(_{\text{Arizona}}\), the conventional AMS was used. The instrument was run with 20 second time resolution, and data points included both chemical speciation and mass loading by mass spectral analysis and particle sizing by species for each data point. In the SP-AMS, particles containing refractory materials (i.e. \(\text{BC}\) and many metals) are vaporized with a 1064 nm laser. The resulting vapor is ionized via electron impact and detected with the HR-TOF-AMS. In addition to the SP-AMS vaporization, the conventional AMS heater (a heated tungsten surface at 600 °C, (Jayne et al., 2000; Canagaratna et al., 2007) was also used to measure the composition of any non-refractory particles. When the instrument was run as a conventional AMS, this was the only heater used.

2.2.3 Potential Aerosol Mass Oxidation Flow Reactor (OFR)
The Potential Aerosol Mass OFR (Aerodyne Research, Inc.; Lambe et al., 2011) is a horizontal 13 L aluminum cylindrical chamber (46 cm long x 22 cm ID) operated in continuous flow mode. Irradiance, relative humidity and temperature in the OFR were measured at the exit flange with UV (TOCON GaP6, sglux) and RH/T (SHT21, Sensiron) sensors, and ozone concentrations were measured with an ozone analyzer (Model 106-M, 2B Technologies).

2.2.4 Aerodyne Mobile Laboratory
The AML, a mobile sampling platform equipped with a suite of research-grade instrumentation, was used to facilitate the in situ OFR-based experiments described here. The AML travelled throughout Idaho, Oregon, Utah, and Arizona during FIREX-AQ, sampling continuously when not conducting OFR experiments. The general sampling strategy was to search for smoke-filled valleys and transect plumes with the AML, using Tuneable Infrared Laser Direct
Absorption Spectrometer (TILDAS, Aerodyne Research, Inc.) (McManus et al., 2011a; McManus et al., 2011b) measurements of hydrogen cyanide (HCN) as a tracer for biomass smoke plumes (Li et al., 2000). Upon identification of a suitable location, the AML parked with the sample inlet on the front of the truck facing into the wind to avoid self-sampling of its own exhaust. A PM$_{2.5}$ cyclone with a small mesh screen to filter out extremely large ash particles was attached to the inlet. A schematic of the OFR experimental setup is given in Fig. 4.

AML positioning, including latitude, longitude, and altitude was measured by a Vector V103 GPS Compass (Hemisphere GNSS, Inc., Scottsdale, AZ). Wind velocity was measured by an ultrasonic anemometer (model 86000, R. M. Young Company, Traverse City, MI). Additional meteorology products were obtained from the NOAA Air Resources Laboratory North American Mesoscale 12 km Archive, and plume ages were approximated using the Hybrid Single-Particle Lagrangian Integrated Trajectory (HYSPLIT) model (Stein et al., 2016). Aerosol composition and mixing state properties were measured with a Soot Particle Aerosol Mass Spectrometer (SP-AMS, Aerodyne Research, Inc./Tofwerk AG, Switzerland) sampled VOCs.

2.3 Experiment Design

The total instrument plus makeup flowrate through the OFR was 6.4 liter min$^{-1}$, corresponding to a calculated mean plug flow residence time of 123 sec. The degree to which plug flow is a valid model for an OFR is the subject of ongoing research, however, this assumption is adequate for the flowrates and experimental setups used here (Mitroo et al., 2018). OFR experiments lasted 1 to 2 hours, during which the reagent inputs were controlled in steps to simulate varying degrees of atmospheric aging. An experiment step consists of two phases, an ambient phase and a reaction phase. During the ambient phase, instruments first sampled ambient air for 5-10 min (depending on the experiment timeline) while LFR/OFR conditions equilibrated for the reaction phase, During the ambient phase, 5 L min$^{-1}$ of makeup flow was pulled through the OFR to reduce stagnation time. Once the ambient phase ended, an electronically actuated 3-way valve was switched to connect the instruments to the OFR, and OFR-processed air was sampled for 5 to 10 min. After each step, the OH$^\cdot$ or NO$_3^\cdot$ exposure was changed, and the above measurements were repeated. After each experiment, the OFR was cleaned out by setting both sets of lamps to maximum output and blowing over the inlet with humidified zero air until AMS measurements of background organic mass were below 0.3 µg m$^{-3}$. To account for dilution and particle wall losses in the OFR refractory black carbon (rBC) monitored with the SP2 was used as a chemically conserved tracer. During all experiments, rBC accounted for ~2% to 5% of total aerosol mass (Figs. S1 and S2).

In the following sections, ambient phases are denoted “ambient_X” and oxidation phases are denoted “OFR_OH_X” for OH$^\cdot$ experiments, and for NO$_3^\cdot$ experiments, the ozone-only step is denoted “OFR_O3”.
and NO\textsubscript{y} oxidation steps are denoted “\textit{OFR NO\textsubscript{3} X}”. “X” indicates the step number. \textbf{Finally, each experiment includes a “background” measurement}, where ambient air was sampled through the dark OFR without oxidant
generation.

2.3.1 NO\textsubscript{3} Experiment Design and Analysis

To generate NO\textsubscript{3}, N\textsubscript{2}O\textsubscript{5} was first generated in the gas phase from the reaction NO\textsubscript{2} + O\textsubscript{3} \rightarrow NO\textsubscript{3} + O\textsubscript{2} followed by the reaction NO\textsubscript{3} + NO\textsubscript{2} \rightarrow N\textsubscript{2}O\textsubscript{5}. In a 152.4 cm long x 2.22 cm ID perfluoralkoxy laminar flow reactor (LFR) coupled to the OFR (Lambe et al., 2020). Separate flows containing NO\textsubscript{2} (1% in N\textsubscript{2}, Praxair) and O\textsubscript{3} were added to the LFR. 
In these experiments, the NO\textsubscript{3} + N\textsubscript{2}O\textsubscript{5} flow rate was set between 0 and 40 cm\textsuperscript{3} min\textsuperscript{-1}, and O\textsubscript{3} was generated by passing 1.8 L min\textsuperscript{-1} of O\textsubscript{3} through an ozone chamber housing a mercury fluorescent lamp (GPH212T5VH, Light Sources, Inc.). The O\textsubscript{3} mixing ratio that was input to the LFR was approximately 250 ppmv during NO\textsubscript{3} –OF R experiments. 
The NO\textsubscript{3} + N\textsubscript{2} and O\textsubscript{3} flow rates were set using mass flow controllers. The N\textsubscript{2}O\textsubscript{5} generated in the LFR thermally decomposed at room temperature inside the OFR to generate NO\textsubscript{3}. The first oxidation step of NO\textsubscript{3} –OFR experiments was with ozone only (“\textit{OFR O3}”) to assess the effect of O\textsubscript{3} exposure on OA composition and optical properties relative to ambient OA. During NO\textsubscript{3} \textit{Arizona}, NO\textsubscript{2} was stepped down from 40 to 20, 5, and 3 cm\textsuperscript{3} min\textsuperscript{-1} to generate the various oxidation time scales (Fig. S3). During NO\textsubscript{3} \textit{Oregon}, inputs of 15 and 5 cm\textsuperscript{3} min\textsuperscript{-1} were used.
The integrated NO\textsubscript{3} exposure, defined as the product of the average NO\textsubscript{3} concentration and the mean OFR residence time (\(\tau_{OFR}\)), was calculated using an estimation equation developed by Lambe et al. (2020):

\[
\log([\text{NO}_3]_{\text{LFR}}) = a + b \log(273.15 + T_{\text{OFR}}) + c \log(T_{\text{OFR}}) \\
\quad + d \log([\text{NO}_2]_{\text{LFR}} + e \log([O_3]_{\text{LFR}} \times T_{\text{OFR}} + f \log(k_{\text{wOFR}, N_2O_5}]) \\
\quad + \log\frac{([\text{NO}_2]_{\text{LFR}})}{([O_3]_{\text{LFR}})} \times (g \log([O_3]_{\text{LFR}})^2 + h \log([O_3]_{\text{LFR}}) \\
\quad - [\text{NO}_2]_{\text{LFR}} \times (i + j \log([O_3]_{\text{LFR}}) + k \log(NO_3R))_{\text{ext}} \\
\quad + l \log([NO_2]_{\text{LFR}}) \times T + m \log([O_3]_{\text{LFR}}) \times \log(k_{\text{wOFR}, N_2O_5}) 
\]  

(1)

Where \(a \) through \(m \) are empirical fit coefficients derived by Lambe et al. (2020) and summarized in Table S1, \(T_{\text{OFR}} \) is the measured temperature in the OFR, \([\text{NO}_2]_{\text{LFR}} \) and \([O_3]_{\text{LFR}} \) were the NO\textsubscript{2} and O\textsubscript{3} mixing ratios input to the LFR (ppmv), \(k_{\text{wOFR}, N_2O_5} = 0.01 \text{ s}^{-1} \) is the assumed N\textsubscript{2}O\textsubscript{5} wall loss rate coefficient in the OFR, and \(\text{NO}_3R_{\text{ext}} \) is the external NO\textsubscript{y} reactivity (s\textsuperscript{-1}), which was calculated from the summed products of ambient VOC concentrations (measured with Vocus) and their and their NO\textsubscript{y} rate coefficients (found in the data repository, see Data Availability section).

Corresponding calculated NO\textsubscript{3} exposures ranged from 1.4×10\textsuperscript{14} to 3.4×10\textsuperscript{14} molec cm\textsuperscript{-3} s, or approximately \textbf{72 to 192 equivalent hours (3 to 8 equivalent days)} of atmospheric oxidation at a 24-hour average NO\textsubscript{3} concentration of 5×10\textsuperscript{4} molec cm\textsuperscript{-3} (Atkinson, 1991).

2.3.2 OH\textsubscript{•} Experiment Design

OH\textsuperscript{•} was generated via photolysis of ambient O\textsubscript{3} and H\textsubscript{2}O at \(\lambda = 185\) nm plus photolysis of O\textsubscript{3} (generated from at \(\lambda = 254\) nm using low-pressure mercury (Hg) lamps):
A fluorescent dimming ballast was used to regulate current applied to the lamps (GPH436T5VH4, Light Sources, Inc.). The dimming voltage applied to the ballast ranged from 1.6 V to 10 V direct current (DC). To extend the range of OH∙ concentrations below what is achievable with one set of lamps at 1.6 VDC, a second set of GPH436T5VH/4 lamps with added segments of opaque heat shrink tubing applied to ~86% of the arc length (Rowe et al., 2020) was used. The OH\text{Arizona} OFR experiment began with the non-attenuated lamps set to maximum output, then switching to 240 the attenuated lamps and stepping the dimming voltage from 10.0 to 5.0, 3.0, 2.0, and 1.6 V (Fig. S4). The OH\text{Oregon} experiment started with the non-attenuated lamps at 10V, then stepping the dimming voltage from 10.0 to 5.0 and 1.6 V. The OH exposure was calculated using Eq. (2) from Rowe et al. (2020):

\[
\log[\text{OH}_{\exp}] = (a + (b - c \times \text{OHR}_{\text{ext}} + e \times \log[O_3] \times \text{OHR}_{\text{ext}}) \times \log[O_3] + \log[H_2O]) + \log\left(\frac{\tau}{124}\right) \tag{2}
\]

Where a through f are fit coefficients tabulated in Table S2, O_3 is the ozone mixing ratio measured at the exit of the OFR (molec cm\textsuperscript{-3}), OHR\text{ext} is the external OH∙ reactivity (s\textsuperscript{-1}), which was calculated from the summed products of ambient VOC concentrations (measured with Vocus) and their and their OH∙ rate coefficients (see Data Availability section), H_2O is the ambient water vapor mixing ratio (%), and \tau is the residence time in the OFR. Corresponding calculated OH exposures ranged from 3.91\times10\textsuperscript{11} to 2.53\times10\textsuperscript{12} molec cm\textsuperscript{-3}s, or approximately 72 to 480 equivalent hours (3 to 20 equivalent days) of atmospheric oxidation at a 24-hour average OH∙ concentration of 1.5\times10\textsuperscript{6} molec cm\textsuperscript{-3} (Mao et al., 2009).

3 Results and Discussion

3.1 Ambient Organic Aerosol MAC(\lambda)

Table 1 summarizes the average MAC(\lambda) values of OA sampled from smoke plumes originating from the Arizona and Oregon wildfires. The absorption Ångström exponent (AAE), which parameterizes the wavelength dependence of absorption and is calculated from the two-parameter formula

\[
\text{AAE}(488 \text{ nm}, 561 \text{ nm}) = -\frac{\log[R_{abs}(488 \text{ nm})]}{\log[R_{abs}(561 \text{ nm})]} \tag{3}
\]

was 0.83 ± 0.25 in Arizona and 0.91 ± 0.21 in Oregon. As shown in Figs. S1 and S2, the rBC mass fraction in the sampled plumes were negligible (<5%) and within the margin of error due to charring of OA in the SP2 (Sedlacek et al., 2018). Therefore, we are confident that the calculated AAE values corresponded to light-
individual ions measured by the AMS can be visualized as a function of NO$_x$ exposure, as does E$_{MAC}$(λ) from NO$_x$ (Oregon, although to a lesser extent because E$_{MAC}$(λ) was higher at lower equivalent time scales. There was a marked difference in the external reactivity (NO$_x$EXT) in the case of BBVOCs to NO$_x$ (or OH). Concentrations are measured by the PTR-MS during the ambient phases and calculated by NO$_x$EXT = $k_{NO_x,prod}[NO_x,prod][OH][BBVOC]$, where $k$ denotes the relevant rate constant. In Arizona, calculated NO$_x$EXT values ranged from 11.6 to 17.6 s$^{-1}$, while in Oregon, NO$_x$EXT ranged from 488 nm to 184.08 ± 4.03 hours. This indicates the presence of high concentrations of biomass burning VOCs (BBVOCs) that were highly reactive to NO$_x$. (Finewax et al. 2017).

The differences in BBVOC external reactivities manifested in different E$_{MAC}$(λ) behavior at the two sites. On the shortest oxidation time scale in Arizona (78.72 ± 0.00 equivalent hours), E$_{MAC}$(488 nm) was 0.99 ± 0.26 and E$_{MAC}$(561 nm) was 1.15 ± 0.79. This is in contrast to Oregon, where at 84.72 ± 9.60 equivalent hours, E$_{MAC}$(488 nm) was 1.47 ± 0.01 and E$_{MAC}$(561 nm) was 1.46 ± 0.01, which we attribute to the variations in BBVOC concentrations between sites. At longer time scales in Arizona, E$_{MAC}$ continued to increase, up to E$_{MAC}$(488 nm) of 1.69 ± 0.38 and E$_{MAC}$(561 nm) of 1.29 ± 0.84. These values were commensurate with results from Oregon at only 82.88 ± 6.71 equivalent hours. Regardless of choice of site, E$_{MAC}$(λ) consistently increased with increasing NO$_x$ oxidation time scales. Li et al. (2020) previously observed this absorption enhancement effect in the laboratory by subjecting biomass burning BrC proxy aerosol derived from wood tar to a similar experimental setup to what was used here. They observed E$_{MAC}$(λ) in the near-UV (330-400 nm) of approximately 2.4, and approximately 6.0 in the visible (400-550 nm), though this high value comes from the ratio of two relatively low MAC(λ) values of 0.6 and 0.1 m$^2$ g$^{-1}$, much lower than the MAC(561 nm) reported here, which, for ambient aerosol was 1.71 ± 0.32 in Arizona and 1.72 ± 0.05 in Oregon.

A breakdown of the chemical speciation from NO$_x$(Arizona) was obtained from the AMS data from before and after the OFR NO$_x$1 step (refer to Fig. S3), the first oxidation step after ozonolysis. During this step, 217 ppm NO$_x$ was flowing into the LFR. NO$_x$EXT before and after this step was 17.56 and 13.90 s$^{-1}$, respectively, for an estimated equivalent age of 138.24 ± 5.23 hours. The individual ions measured by the AMS can be visualized for oxidative enhancement or depletion on a log-log scatterplot, shown with markers in Fig. S5, and with individual
While knowledge of the individual m/z enhancement and depletion may inform future investigations, it is perhaps more illustrative to consider ion families writ large. Figure 6 shows the enhancement and depletion of the ion families in Figs. S5 and S6 on the basis of total ion mass in that family. Enhancement is calculated by summing the relative abundances of all ions within a family and taking the ratio of oxidized to ambient, similar to how $E_{\text{MAC}}(\lambda)$ is calculated.

[Figure 6]

The CHO$_{\gt 1}$N ("O$_{\gt 1}$" indicates more than one oxygen atom in a molecule containing one or more atoms of C, H, and N) family is enhanced by 211% and CHO$_{1}$N ("O$_{1}$" indicates a single oxygen atom in a molecule containing one or more atoms of C and H) by 132% through the OFR, with a corresponding diminishment in CHO$_{\gt 1}$ and CHO$_{1}$ (where again, "O$_{\gt 1}$" and "O$_{1}$" indicate the quantity of oxygen atoms in molecules of one or more atoms of C and H) to 79% and 91%, respectively. This does not imply that all CHO$_{1}$N species come from CHO$_{1}$ (or CHO$_{\gt 1}$N from CHO$_{\gt 1}$, similarly). The addition of nitrogen-containing functional groups is likely the cause of the observed light absorption enhancement, since nitrogenated aromatic hydrocarbons form during reactions with NO$_3$ (Li et al., 2019) and can act as chromophores, increasing light absorption (Jacobson, 1999; Laskin et al., 2015; Xie et al., 2019).

### 3.2.1 O$_3$ Oxidation Effects

The first step in the NO$_3$ experiments was an O$_3$-only oxidation experiment in case the effects of ozonolysis on biomass burning smoke were significant. Since the NO$_3$ oxidation steps carry a significant amount of residual O$_3$, the contribution of O$_3$ to changes in absorption behavior should be quantified and treated separately from NO$_3$. Li et al. (2020) performed a similar experiment in their laboratory oxidation studies and found that NO$_3$ oxidation was the dominant chemical transformation mechanism when compared to O$_3$. They further reported a slight decrease in $E_{\text{MAC}}(405 \text{ nm})$ quantified by a reduction in the imaginary refractive index from 0.017 ± 0.005 to 0.011 ± 0.003.

However, differences in how Li et al. performed their experiments (by exposing aerosol to 35 ppbv O$_3$ for 10.6 hours) preclude any direct comparison to the short O$_3$ exposure time scales performed during FIREX-AQ. $E_{\text{MAC}}(\lambda)$ due to O$_3$ during NO$_3$, Arizona, was 1.06 ± 0.96 and 1.05 ± 0.94 for 488 and 561 nm, respectively, indicating that O$_3$ effects during the OFR experiments were negligible, or at least dominated by NO$_3$.

### 3.3 Daytime Oxidation

Compared to the NO$_3$ experiments, a much broader range of equivalent atmospheric aging was mimicked in the OH experiments. NO$_3$ is a comparatively selective oxidant, while OH tends to oxidize nearly all organic aerosol it comes in to contact with. Between approximately 72 and 480 equivalent hours (3 and 20 equivalent days) of oxidation were performed. Average surface wind speeds were 2.98 m s$^{-1}$ in Arizona and 0.43 m s$^{-1}$ in Oregon. As expected, $E_{\text{MAC}}(\lambda)$ for these experiments nominally showed light absorption diminishment for most experiments, however, $E_{\text{MAC}}(\lambda)$ exceeded unity between 91.06 ± 1.30 and 417.86 ± 26.95 hours. This effect of initial darkening and subsequent lightening has been reported previously (Sumlin et al., 2017a; Hems et al., 2020).
absorption enhancement mechanism was outside the scope of Sumlin et al. (2017) who rather focused on the likely mechanisms of BrC light diminishment, however Hems et al. (2020) posit that the increase in absorbance is linked to the formation of aromatic dimers and functionalization reactions. Hems et al. report that the absorption enhancement was observable up to 11 equivalent hours of OH\textsuperscript{-} exposure, and diminished with a net exposure of up to 42 hours. It should be noted that the samples analyzed by Hems et al. was only the water-soluble portion, obtained by gathering BrC on a filter and extracting with purified water. Furthermore, the OH\textsuperscript{-} oxidation was carried out by adding hydrogen peroxide to the extract solution and exposing it to UV lamps. The OH\textsuperscript{-} oxidation performed by the OFR during FIREX is far less controlled, given the dynamic nature of the plumes we sampled. Figure 7 shows $E_{\text{MAC}}(\lambda)$ at 488 and 561 nm for all OH\textsuperscript{-} experiments. The data is summarized in Table 3.

While OH\textsubscript{EXT} values were large, it is noteworthy that they were typically exceeded by NO\textsubscript{3,EXT} values, which, as noted in the previous section, indicates the presence of BBVOCs that are more reactive toward NO\textsubscript{3} than toward OH\textsuperscript{-}. The exact nature of these sensitivities requires further research.

The same scatterplot analysis was applied to the OFR\textsubscript{1} step (refer to Fig. S4) of the OH\textsubscript{Arizona} experiment, however, it is less illustrative than with NO\textsubscript{3} because the primary driver of MAC(\lambda) diminishment is fragmentation reactions. Before this step, OH\textsubscript{EXT} was 74.95 s\textsuperscript{-1} and after, it was 59.37 s\textsuperscript{-1}, giving an approximate equivalent age of $438.50 \pm 180.86$ hours. The enhancement ratios of the individual ion families show a decrease in CHO\textsubscript{N} and an increase in CHO\textsubscript{gtN}, though to a lesser degree than under NO\textsubscript{3} aging. The ambient CHO\textsubscript{gtN} mass fraction was approximately 25% higher in the NO\textsubscript{3,Arizona} as well – the comparatively lower relative abundances of nitroaromatics during OH\textsubscript{Arizona} (both pre- and post-OFR\textsubscript{1}) may obfuscate any meaning in the enhancement ratios.

Figure 8 shows the ion family enhancement ratios through the same OFR\textsubscript{1} step corroborating the conclusions drawn from the scatterplots.

4 Conclusions and Future Work - Synthesizing Daytime and Nighttime Aging

The observations of $E_{\text{MAC}}(\lambda)$ and the associated chemistry of smoke OA sampled as part of the FIREX-AQ ground campaign represent the first attempt to use an OFR in a mobile setting to sample biomass burning at their source, as well as the first application of the novel MIPN v1 to a field study. Observations track closely with previous laboratory studies. These results show the difficulty in naively applying a particular aging model to atmospheric aerosol to constrain their long-term behavior in climate models. Aerosol does not age along any single pathway for more than half of a diurnal
cycle: at night, oxidative aging of OA by NO\textsubscript{3} increases MAC(λ), whereas daytime oxidative aging by OH· decreases MAC(λ). Overall, our results suggest that explicit characterization of the effect of diel aging on atmospheric aerosol optical, chemical, and physical properties represents the best possible input to climate models.

Data availability. All experimental data, including MIPN; SP-AMS; SP2; and Vocus PTR-MS measurements, rate constants, and data tables used to calculate external reactivities are available for download at doi:10.17632/5mr43vbks3.1 (Sumlin, 2021).

Supplement. Includes eight figures detailing rBC fraction observed during experiments (S1 and S2), sample timelines for oxidation experiments (S3 and S4), and AMS signal enhancements for various ion families upon oxidation (S5 through S8). Also includes two tables (S1 and S2) with fit coefficients for Eqs. (1) and (2).

Author contributions. RKC and BS conceived of the study and its design. RKC and AL provided guidance and supervision for carrying out the research tasks, interpretation of results, and contributed to the preparation of the manuscript. BS, EF, NJS, FM, CD, and SH performed the experiments. BS performed the data analysis, developed the figures, and led the preparation of the manuscript. All authors were involved in the editing and proofreading of the manuscript.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements

The authors would like to acknowledge Tara Yacovitch, Rob Roscioli, Jordan Krechmer, and Tim Onasch of Aerodyne Research, Inc. and Art Sedlacek III of Brookhaven National Laboratory for their effort in processing and contributing AML data to the public FIREX-AQ repository. Chakrabarty and his group acknowledges support from the US National Science Foundation (AGS-1455215 and AGS-1926817), the US Department of Energy Atmospheric System Research program (DE-SC0021011), and the NASA ACCDAM program (NNH20ZDA001N). Sumlin acknowledges support from NASA Earth System Science Fellowship (80NSSC18K1414).

Figure 1: Map of the Grand Canyon region overlaid with HCN concentration (ppb, color scale), elevation (HCN marker size, larger is higher AMSL), fire origin locations from Incident Information System (white triangles), OH$_{36.609}$ experiment location (white star), and fire boundary maps for 08/20/2019. Based on HYSPLIT back-trajectories, the plume for this experiment was less than one hour old, though surface concentrations of smoke were comparatively lower since the nocturnal boundary layer had lifted. Background map is from USGS EarthExplorer, and fire map overlays are from the National Wildfire Coordinating Group’s Incident Information System (InciWeb).
Figure 2: As with Figure 2, but for NO$_3$-Atomic on 08/22/2019. Based on HYSPLIT back-trajectories, the plume for this experiment was again less than one hour old, though smoke that had settled in the valley under the nocturnal boundary layer may have been older. Background map is from USGS EarthExplorer, and fire map overlays are from the National Wildfire Coordinating Group’s Incident Information System (IncidentWeb).
Figure 3: As with Figures 2 and 3, showing fire ignition point (white triangle), OHOregon and NO3Oregon experiment locations (white stars), and fire boundary maps for 08/26/2019. HYSPLIT back-trajectories again show the plumes for these experiments were much less than one hour old. Background map is from USGS EarthExplorer, and fire map overlays are from the National Wildfire Coordinating Group’s Incident Information System (InciWeb).
Figure 4: A schematic of the general experimental setup aboard the AML showing instruments, reactors, reagents, and other hardware.

Figure 5: MAC($\lambda$) Enhancements at 488 and 561 nm during NO$_3$Arizona (triangles) and NO$_3$Oregon (square and circle; the circle is partially obscured by the square). The gray dashed line is the “no enhancement” line. The Arizona experiment data shows an increasing trend in MAC($\lambda$) with increasing equivalent age. The Oregon data on its own does, as well, but in
context of the Arizona data, the chemical species present in the smoke plume in Oregon appear to have been much more reactive towards $\text{NO}_3^\cdot$. Equivalent photochemical age is calculated from the $\text{NO}_3^\cdot$ exposure in the OFR and assuming an average ambient $\text{NO}_3^\cdot$ concentration of $5 \times 10^8 \text{molec cm}^{-3}$ (Atkinson et al, 1991).

Figure 6: Enhancement and depletion of ion families measured by the AMS during $\text{NO}_3^\cdot$ oxidation. $\text{CHO}_2\text{N}$ and $\text{CHO}_3\text{N}$, while present in lower relative abundances, showed the largest enhancement through $\text{NO}_3^\cdot$ oxidation.
Figure 7: MAC(λ) Enhancements at 488 and 561 nm during OH_{Arizona} (triangles) and OH_{Oregon} (square and circle, which is partially obscured). The gray dashed line is the “no enhancement” line. The shows an initial diminishment, then subsequent increasing to decreasing trend in MAC(λ) with increasing equivalent age. Equivalent photochemical age (hours) is calculated from the OH· exposure in the OFR and assuming an average ambient OH· concentration of 1.5×10^6 molec cm\(^{-3}\) (Mao et al, 2009).
Figure 8: Enhancement and depletion of ion families measured by the AMS during OH oxidation. CHO₃N is depleted while CHO₄N is enhanced, however, both these families are present in low relative abundances which may exaggerate the enhancement ratio.
Table 1: Study-average values of mass absorption coefficients (MAC, m² g⁻¹) from Arizona and Oregon. Errors are one standard deviation.

| Wavelength | Arizona MAC | Oregon MAC |
|------------|-------------|------------|
| 488 nm     | 1.93 ± 0.33 | 1.95 ± 0.41|
| 588 nm     | 1.71 ± 0.32 | 1.72 ± 0.05|

Table 2: E_{MAC}(488 nm) and E_{MAC}(561 nm) for NO₃⁻ oxidation experiments. Asterisks denote NO₃, Oregon. All others taken during NO₃, Arizona, and the dagger indicates O₃-only oxidation.

| Equivalent eight hours | E_{MAC} at λ = 488 nm | E_{MAC} at λ = 561 nm |
|------------------------|------------------------|------------------------|
| 84.72 ± 0.60*          | 1.47 ± 0.01            | 1.46 ± 0.01            |
| 92.88 ± 0.60*          | 1.67 ± 0.01            | 1.65 ± 0.01            |
| 46.114 ± 0.02*         | 1.72 ± 0.22            | 1.39 ± 0.79            |
| 2.61 ± 0.08 ± 0.02     | 1.69 ± 0.38            | 1.29 ± 0.84            |
| n/a                    | 1.06 ± 0.96            | 1.05 ± 0.94            |

Table 3: E_{MAC}(488 nm) and E_{MAC}(561 nm) for OH⁻ oxidation experiments. Asterisk denotes OH, Oregon. All others taken during OH, Arizona.

| Equivalent eight hours | E_{MAC} at λ = 488 nm | E_{MAC} at λ = 561 nm |
|------------------------|------------------------|------------------------|
| 7.5 ± 0.5*             | 0.88 ± 0.02            | 0.94 ± 0.02            |
| 3.20 (1.06 ± 0.05)     | 1.05 ± 0.02            | 1.00 ± 0.02            |
| 4.43 ± 0.35*           | 0.97 ± 0.03            | 0.97 ± 0.03            |
| 2.24 ± 0.2 ± 0.06     | 0.88 ± 0.02            | 0.99 ± 0.02            |
| 10.24 ± 0.54 ± 0.03*  | 0.72 ± 0.08            | 0.73 ± 0.01            |
