ABSTRACT

We report the spectroscopic confirmation of a submillimeter galaxy (SMG) at z = 4.547 with an estimated L_\text{FIR} = 0.5 - 2.0 \times 10^{13} L_\odot. The spectra, mid-IR, and X-ray properties indicate the bolometric luminosity is dominated by star formation at a rate of >1000 M_\odot yr^{-1}. Multiple, spatially separated components are visible in the Ly\alpha line with an observed velocity difference of up to 380 km s^{-1} and the object morphology indicates a merger. The best-fit spectral energy distribution and spectral line indicators suggest the object is 2-8 Myr old and contains >10^{10} M_\odot of stellar mass. This object is a likely progenitor for the massive early-type systems seen at z ~ 2.

1. INTRODUCTION

The study of galaxies detected at millimeter and submillimeter wavelengths is one of the most rapidly developing fields in observational astronomy. It is now known that a large fraction of the star formation activity is enshrouded in dust, with the star formation rate (SFR) being directly proportional to the far-infrared (FIR) luminosity of galaxies, modulo possible contributions from an active galactic nucleus (AGN) (Hughes et al. 1998). Surveys performed at millimeter wavelengths directly probe the FIR luminosity, and hence the amount of star formation. Furthermore, the shape of the galaxy spectral energy distributions (SEDs) at rest-frame millimeter wavelengths results in a negative K-correction in the range 0.5 < z < 10. Therefore a flux-limited survey is equivalent to an SFR-limited survey at these redshifts (Blain et al. 2002).

The current redshift distribution of millimeter galaxy peaks at z ~ 2, with very few galaxies at z > 3 (Chapman et al. 2005; Pope et al. 2005; Aretxaga et al. 2007). However, the small bandwidth of current millimeter-wave spectrographs makes it very difficult to measure redshifts directly, and the low angular resolution of millimeter single-dish imaging leads to multiple optical counterparts for the same source. As a result, millimeter surveys have relied on high-resolution radio data to identify the optical counterparts for subsequent spectroscopic follow-up. This leaves 35%-70% of the population of millimeter-selected galaxies at milli-Jansky flux levels unidentified and potentially at higher redshift (Wang et al. 2007; Younger et al. 2007).

In this Letter we report the discovery of a millimeter galaxy with a spectroscopic redshift of z = 4.547 that appears to be dominated by star formation. This is the highest redshift galaxy detected at millimeter wavelengths not associated with an optically bright quasar. The object was independently selected as a Lyman break galaxy (K.-S. Lee et al. 2008, in preparation) for spectroscopic follow-up, a millimeter source, and a radio source (Carilli et al. 2008). The source reported here is unusual for millimeter sources because it has several nearby optically bright counterparts which were selected as V-band dropouts and is unusually luminous which allows for a radio detection. However, the confirmation of this object suggests the population of sources with similar radio to millimeter flux ratios and optical colors may also be at high redshifts.

We assume a H_0 = 70, \Omega_\Lambda = 0.7, \Omega_m = 0.3 cosmology and a star formation rate integrated across a Salpeter (1955) IMF from 0.1 to 100 M_\odot throughout this Letter.

2. DATA

Observations at \lambda = 1.1 mm with an average rms noise of 1.3 mJy were obtained with the AzTEC (Wilson et al. 2008) camera at the James Clerk Maxwell Telescope (JCMT) (Scott et al. 2008). Additional observations were obtained by the MAMBO camera on the IRAM 30 m telescope with an rms of 0.67 mJy and a positional accuracy of <5" (E. Schinnerer et al., in preparation). Ground-based optical and near-infrared imaging in 22 bands, Hubble Space Telescope, Spitzer, and Very Large Array images were obtained as part of the COSMOS survey as described in Capak et al. (2007), Scoville et al. (2007), Sanders et al. (2007), and Schinnerer et al. (2007), respectively. Additional deep J and K_s data were obtained with

* All limits are 1σ limits.
* A nearby bright source was modeled and subtracted to make this measurement; the formal upper limit is 70 μJy if the nearby source is not subtracted.

The optical spectra were taken on the Keck II telescope using the DEIMOS instrument with a 1″ slit width, the 830 line mm^{-1} grating (3.3 Å FWHM resolution), and the OG550 blocking filter to optimize red throughput. The data were collected in eight 1800 s exposures (4 hr total integration) under photometric conditions with 0.4″–0.6″ seeing. The object was dithered along the slit by ±3″ between exposures to improve background subtraction. The data were reduced with a modified version of the DEEP2 DEIMOS pipeline (Marinoni et al. 2001).

An image of the continuum and Lyα emission is shown in Figure 1 and indicates emission from all components of the source. The 2D and 1D spectra are shown in Figures 2 and 3, respectively. Lyα emission is detected from both the compact and extended portions of the object with a velocity gradient across the slit. Lyα emission from the diffuse region is redshifted with respect to the compact source, and a deep Lyα absorption feature is present at a redshift corresponding to other absorption features seen in the spectra. The dispersion of distinct peaks in the Lyα emission is 380 km s^{-1} and the line asymmetry indicates outflow winds of up to ~1800 km s^{-1}, typical of a merger with heavy star formation. Several interstellar absorption features are clearly seen in the continuum yielding a best-fit redshift of 4.547 ± 0.002, but the dispersion in the Lyα line suggests some components could be ±0.02 from the continuum redshift.

A foreground object with an i' band flux of 0.58 μJy is visible to the west of our source in the B-band image (see Fig. 1) and its spectrum shows [O ii] emission at z = 1.41. The mass of this system is too low to significantly gravitationally lens our

FIG. 1.—Images in Bγ, Lyα, i', ACS F814W, z', Ks, and 3.6 μm are shown for 6′ × 6′ (39.4 kpc) around the source. The radio position is marked with a cross and a foreground object is marked with an arrow. 1.4 GHz Radio contours are overlaid on the ACS-band image in the rightmost panel. The Lyα image is generated by subtracting the r' continuum image from the IA679 image which is centered on the Lyα line. The 3.6 μm (rest-frame optical) flux is centered on the radio position and diffuse i' and z' (rest-frame UV) flux. A UV bright knot is visible down and to the left (0.6″ to the SE) of the radio position and contains 73% of the UV flux. The Lyα emission is more extended than the UV emission seen in the i' band and originates from both the UV bright knot and the radio position but not the foreground objects. Note that the UV bright knot is absent in the Ks-band image, indicating a very young age.

FIG. 2.—The 2D spectra of the object around the Lyα line is shown on the right along with the ground-based z'-band image on the left with the slit position marked in blue, the radio position marked with a magenta cross, and the foreground object indicated by a magenta arrow. The red lines are spaced at 0.4″ intervals, which is comparable to the spatial resolution of the spectra, and the black bar on the bottom right has a length of 1 Å in the rest frame. Lyα emission is coming from all portions of the source and there is a clear velocity gradient along the slit. The Lyα absorption feature at the physical position of the bright continuum emission and the multiple peaks in the Lyα line.
O stars, placing the age of the burst at a few Myr (Pettini et al. 2000). Note the absence of a common forbidden He $\text{He}^{\text{ii}}$ generated in shocked gas, suggesting that we are not looking through a significant column of gas. The presence of the Si $\text{Si}^{\text{iv}}$ from a compact (based and images, which are more sensitive to extended and a region of extended emission is visible in the ground-

The rest-frame ultraviolet (UV) properties indicate a merger, typical of star-forming millimeter sources seen at $z \sim 2$ (Chapman et al. 2005; Pope et al. 2005; Aretxaga et al. 2007). At least two distinct components are visible in the ACS image, and a region of extended emission is visible in the ground-based $i^\prime$ and $z^\prime$ images, which are more sensitive to extended emission than the $HST$ data. The rest-frame UV is centered at $10^{\text{0.00}}54.516\text{.}^\prime$, $+234\text{.}35.17\text{.}^\prime$ with the radio and rest-frame optical emission centered at $10^{\text{0.00}}54.48\text{.}^\prime$, $+234\text{.}35.9\text{.}^\prime$.

The majority (73%) of the rest-frame UV flux originates from a compact ($< 2.7$ kpc) knot of emission at the southeast corner of the object, with the remaining UV emission extended over 17.7 kpc (2.7$^\prime$), while the rest-frame optical (Spitzer IRAC) flux of the source is centered on the diffuse UV and radio emission. The IA679 filter corresponds to the rest-frame Ly$\alpha$ line and shows strong emission from all components of the source and an extended Ly$\alpha$ halo around the source (see Fig. 1). In addition, a significant excess of flux is measured in the 3.6 $\mu$m band which is centered on the H$\alpha$ line at $z = 4.547$. The Ly$\alpha$ image, the 3.6 $\mu$m excess, and the optical-IR colors of the diffuse region are consistent with all components residing at $z = 4.547$.

The possible presence of H$\alpha$ in the 3.6 $\mu$m band and [O $\text{II}$] in the $K_s$ band combined with the low S/N of the $J$ band and multiple components with different SEDs make it difficult to constrain the age and mass of this object with stellar models because the 4000 $\AA$ break strength is degenerate with the line ratio in some cases. To reduce these degeneracies H$\alpha$ and [O $\text{II}$] line flux is added to the stellar models in proportion to the unobscured UV star formation rate (Kennicutt 1998). The diffuse portion of the source fades rapidly between the $K_s$ and $z^\prime$ bands, indicating significant obscuration. The UV compact region is not detected redward of the $z^\prime$ band, indicating a very young (<5 Myr old) stellar population and little dust obscuration.

A two-component fit to the total integrated light produced poor results. The UV and optical light are spatially separated, but the best-fit model places the majority of both the UV and optical light in a single unobscured <0.1 Gyr old population. To overcome this degeneracy we attempt to deconvolve the UV bright knot and the diffuse component of the source. Flux measurements were made in all of the ground-based images for the UV diffuse portion of the source using a 1$^\prime$ diameter aperture on the original stacked images without PSF matching (Capak et al. 2007). An aperture correction of 1.4 mag, based on the ACS morphology, was then applied. A Maraston (2005, hereafter M05) or Bruzual & Charlot (2003, hereafter BC03) single-burst model with solar metallicity, a Salpeter IMF, and a Calzetti et al. (2000) extinction law were then fit to these and the IRAC measurements. The model fluxes were then subtracted from the total flux, and a second model was fit to the remaining flux. The resulting fits are tabulated in Table 2 and shown in Figure 4.

The present data do not constrain the peak or shape of the FIR emission, so the total luminosity is uncertain, but the millimeter and 24 $\mu$m data imply an infrared luminosity of $(0.5-2) \times 10^{15} L_{\odot}$, and a corresponding SFR of 1000-4000 $M_{\odot}$ yr$^{-1}$ (Dale & Helou 2002; Chary & Elbaz 2001; Carilli & Yun 1999). The radio flux gives a second estimate of the SFR independent of dust obscuration at $3700 \pm 700 M_{\odot}$ yr$^{-1}$ assuming a radio spectral slope of $-0.8$ (Kennicutt 1998). Finally, assuming the excess flux in the 3.6 $\mu$m band is due to H$\alpha$ originating from the diffuse com-

| Emission Source | Age (Myr) | Average Mass ($M_\odot$) | UV SFR ($M_\odot$) | $\chi^2$ | Model |
|-----------------|-----------|-------------------------|-------------------|---------|--------|
| Diffuse .......  | 6.5       | 1.4                     | $1 \times 10^{30}$ | 3200 $\pm$ 550 | 24.3   | M05    |
|                 | 7.6       | 1.5                     | $2 \times 10^{30}$ | 4200 $\pm$ 730 | 24.7   | BC03   |
| Compact ....... | 2.5       | 0.0                     | $2 \times 10^{3}$ | 250 $\pm$ 20   | 54.5   | M05    |
|                 | 2.9       | 0.0                     | $6 \times 10^{3}$ | 250 $\pm$ 20   | 55.7   | BC03   |

Fig. 3.—Optical spectrum of the source (black) is shown along with the composite LBG spectrum (red) from Shapley et al. (2003). The subtracted sky spectrum is shown in green for comparison and the atmospheric A and B absorption bands are marked with boxes. The inset panel on the right shows the region around the Ly$\alpha$ line. Lines from the interstellar medium and stellar photospheres such as O $\text{I}$, O $\text{II}$, C $\text{II}$, C $\text{IV}$, Si $\text{II}$, Fe $\text{II}$, and He $\text{II}$ are clearly visible in the spectra. The presence of the Si $\text{IV}$ 1297 $\AA$ and C $\text{IV}$ 1549 $\AA$ P Cygni lines, along with the He $\text{II}$ 1640 $\AA$ emission lines, indicates the presences of both Wolf-Rayet and O stars, placing the age of the burst at a few Myr (Pettini et al. 2000). Note the absence of a common forbidden He [i] absorption feature at 1264 $\AA$ which is generated in shocked gas, suggesting that we are not looking through a significant column of gas.
inated by star formation. The UV and radio morphology suggest the models because the Hα determined values. This last measurement is largely independent of component, we derive a dust-corrected star formation rate of 2900 M⊙ yr⁻¹ kpc⁻², within the range of locally observed starbursts (Solomon & Vanden Bout 2005; Sanders & Mirabel 1996). However, without a high-resolution map of the millimeter emission and gas it is not possible to form a clear picture of how the star formation is dominated by star formation. The UV and radio morphology suggest a star formation rate density of 15–50 M⊙ yr⁻¹ kpc⁻², within the range of locally observed starbursts (Solomon & Vanden Bout 2005; Sanders & Mirabel 1996). However, without a high-resolution map of the millimeter emission and gas it is not possible to form a clear picture of how the star formation is distributed. No X-ray flux is detected in a 200 ks Chandra exposure placing the X-ray–to–FIR luminosity ratio in the star-formation-dominated regime (Alexander et al. 2003, 2005), and the radio-to-FIR flux ratio falls on the local starburst relation (Yun et al. 2001). However, the limit on the X-ray–to–radio luminosity ratio does not rule out an AGN. The SFR inferred by the diffuse UV and optical emission can explain the FIR emission if the two are spatially related. Finally, the Lyα line is narrow and AGN emission lines such as broad C iv or N v are not observed in the optical spectra, so any AGNs must either be heavily obscured and/or outside the spectrograph slit.

4. IMPLICATIONS FOR GALAXY FORMATION

This object is a likely progenitor for the massive (>10¹¹ M⊙), old (>2 Gyr), early-type systems seen in large numbers at z ~ 2 (McGrath et al. 2007; Kong et al. 2006; Daddi et al. 2005; Cimatti et al. 2004). The morphology and spectral properties of the passive galaxies indicate they formed in a single burst at z > 4 (Cimatti et al. 2008; Stockton et al. 2008; Daddi et al. 2005). However, the density of passive z ~ 2 systems is ~10⁻⁴ Mpc⁻³ (Kong et al. 2006; Daddi et al. 2005), which is too high to be explained by the previous millimeter source redshift distribution (Cimatti et al. 2008).

The discovery of this object and other recent studies suggest the fraction of z > 4 millimeter sources may be higher than previously thought. An 850 μm flux limited sample is equivalent to a star formation rate limited sample at 0.5 < z < 7.5 and the z ~ 2 objects must have formed by z ~ 4 in order to have sufficient time to evolve into passive systems. With this redshift range and a star formation duration (duty cycle) of 50 Myr, a surface density of ~200 objects per square degree is required for these sources to be progenitors of the z ~ 2 passive galaxy population. Objects brighter than 4 mJy at 850 μm would have a sufficiently high SFR to form >10¹¹ M⊙ passive systems within 50 Myr and the density of such sources is sufficient to form the z ~ 2 passive galaxies if ~30% of them are at z > 4 (Borys et al. 2003). This fraction is well within the range recent studies place at z > 4 (Younger et al. 2007; Wang et al. 2006; Chapman et al. 2005).

Support for this work was provided by the Spitzer Science Center which is operated by the Jet Propulsion Laboratory (JPL), California Institute of Technology, under NASA contract 1407, NASA through contract 1278386 issued by the JPL, and NASA grant HST-GO-09822.
