(Dated: June 29, 2018)

One of the exciting features of two-dimensional (2D) materials is their electronic and optical tunability through strain engineering. Previously we found a new class of 2D ferroelectric Rashba semiconductors PbX (X=S, Se, Te) with tunable spin-orbital properties. In this work, based on our previous tight-binding (TB) results, we derive an effective low-energy Hamiltonian around the symmetry points that captures the effects of strain on the electronic properties of PbX. We find that strains induce gauge fields which shift the Rashba point and modify the Rashba parameter. This effect is equivalent to the application of in-plane magnetic fields. The out-of-plane strain, which is proportional to the electric polarization, is also shown to modify the Rashba parameter. Overall, our theory connects strain and spin-splitting in ferroelectric Rashba materials, which will be important to understand the strain-induced variations in local Rashba parameters that will occur in practical applications.

I. INTRODUCTION

Monolayers and heterostructures of two-dimensional (2D) materials with spin-orbit interaction offer promise for observing many novel physical effects. In particular, it has been proposed that topological insulators or semiconductors with Rashba interactions coupled with superconductors may host Majorana fermions, which are potential building blocks for topological quantum computers.

In addition to 2D materials that exist in the hexagonal phase, such as graphene and the transition metal dichalcogenides (TMDCs), 2D materials with square lattices have been successfully fabricated. Recently, the Rashba effect has been observed in thin layers (6–20 nm) of lead sulfide (PbS), where an external electric field is used to break the inversion symmetry. However, the spin-splitting is not large. In our previous work based on density functional theory (DFT) calculations, we found that lead chalcogenide monolayers PbX (X=S, Se, Te) have large Rashba coupling λ ~ 1 eVÅ in their non-centrosymmetric buckled phase. In addition, the spin texture can be switched in a non-volatile way by applying an electric field or mechanical strain, which puts these materials into the family of ferroelectric Rashba semiconductors (FERSCs). This spin-switching mechanism has recently been observed experimentally in thin films of GeTe where the surface is engineered to have either an inward or outward electric polarization.

In reality, monolayers experience strains due to substrates, defects, and so on, where local strains may change the electronic properties of monolayers. Important examples of such effects are pseudo-Landau levels in graphene blisters and band gap shifts in biaxially strained MoS2. Recently, spatial variations of Rashba coupling due to variations in local electrostatic potentials were reported in InSb. To date, most theoretical studies of lead chalcogenide monolayers have been based solely on DFT calculations. However, because DFT is limited to the simulation of small systems, typically several nanometers, it is difficult to model inhomogeneous strains over large spatial areas using DFT.

In this paper, based on our previous tight-binding (TB) model, we develop a continuum model to predict strain-induced changes in the spin and electronic properties of buckled PbX monolayers. We have also performed DFT calculations to validate our TB predictions. Due to the buckled structure of PbX, the angular dependence becomes important as the relative angle between hybrid orbitals of the top and bottom layer can change substantially. We note that some studies on (non-buckled) SnTe and PbX (X=S, Se, Te) rock-salt type materials have incorporated strain effects in the TB, but did not include the changes in hopping parameters due to angle changes.

In contrast, our TB formulation incorporates the effects due to changes in (i) bond distance and (ii) angle between nearest neighbors as well as (iii) lattice vector deformation. In the low-energy Hamiltonian, the biaxial (or uniaxial) strains can be described as gauge fields, which are equivalent to, by minimal coupling, the application of in-plane magnetic fields. The out-of-plane strain is directly related to the out-of-plane polarization and this also modifies the Rashba parameter. Within this framework we are able to quantify the Rashba fields in terms of the strain fields.

II. TIGHT-BINDING

Lead chalcogenide PbX (X=S, Se, Te) consists of two atoms per unit cell, denoted by A and B atoms, respectively. Lead is a heavy atom (Z(Pb)=82), and it is cru-
socius when the two sublattices are not equivalent. The spin degree of freedom, and the momentum degree of freedom, and space is \( X = 16 \times 16 \), with new basis of coordinates.

For the two atom \( AB \) unit cell shown in Fig. 1(a), the relevant orbital basis involves \( \{ s_A^z, p_x^A, p_y^A, p_z^A, s_B^z, p_x^B, p_y^B, p_z^B \} \). To write down the hopping matrix, we use the Slater-Koster matrix elements. Projecting the Hamiltonian onto the conduction band subspace we obtain the effective Rashba-like Hamiltonian

\[
H_{\text{eff}}^{mn} = \lambda \left( \mathbf{q} \times \mathbf{\sigma} \right) \cdot \left( \frac{\Psi^\dagger_{mn}}{\Phi_{mn}} \right),
\]

where \( \mathbf{q} \) is the momenta, \( \mathbf{\sigma} = (\sigma_x, \sigma_y, \sigma_z) \), \( \lambda \equiv a \sin \theta \Delta c_1 c_2 \) is the Rashba parameter, and \( \Delta = V_{ppp} - V_{ppx} \). The coefficients \( c_0, c_1, c_2 \) can be obtained from the DFT calculations. Since we know the buckling angle \( \theta \) we can evaluate \( \Delta \). All of the relevant (unstrained) parameters are tabulated in Appendix A.1.

### III. STRAIN-INDUCED GAUGE FIELDS

Since the SOI is independent of lattice distortions, in this derivation we will focus on the spinless Hamiltonian and then reintroduce the spin terms. We will focus on the conduction band only, as the changes in valence band should be similar.

Under deformation a vector connecting two points in a unit cell \( i \) can be approximated as \( \mathbf{r}'_j - \mathbf{r}'_i \approx \mathbf{\delta}_j + \mathbf{\delta}_j \nabla \mathbf{u}(\mathbf{r}_i) \), where \( \mathbf{u} = (u_x, u_y, u_z) \) is the displacement vector, and \( \nabla \mathbf{u} = \mathbf{\dot{e}} + \mathbf{\ddot{w}} \). In this work we focus on deformation that...

---

**FIG. 1.** (a) Schematic top and side views of a buckled \( AB \) monolayer. (b) Undeformed and deformed Brillouin zone as the monolayer is stretched in the \( x \) and \( y \) direction. (c) Representative band structures of strained PbS along symmetry points \( X-Y-M-X \) and (d) close to \( M \). (e) Relative change in the Rashba parameters obtained from DFT calculations as a function of strain \( \epsilon \) for PbS, PbSe, and PbTe. Energy spin-splitting of PbS for isotropic strains of (f) \( \epsilon = 0.00 \) and (g) \( \epsilon = 0.10 \). It can be seen that the \( M \) points are originally located at \(|k_{x,y}| = \pi/a_0 \) and shifted closer to the center under a strain of \( \epsilon = 0.10 \).
In-plane strains

Out-of-plane strains

FIG. 2. Schematic changes in the Rashba dispersions due to (a) in-plane strains and (b) out-of-plane strains. The linear Rashba dispersions at the $M$ for unstrained systems are colored blue. Under positive in-plane strains, the Rashba points shift closer to $\Gamma$ and the strength of Rashba parameters decrease (smaller slope) with increasing strains. On the other hand, under out-of-plane strain, the strength of Rashba parameters increases with increasing uniaxial out-of-plane strain while the Rashba points do not shift.

does not involve local rotation $\vec{\omega} = 0$. Similarly, between two lattice vectors $R'_j - R'_i \simeq a^i + a^i \cdot \nabla u(R_i)$. Alterations in bond distance will result in changes in the hopping energies. Since studies of lead chalcogenides under strain are very limited, we follow the Wills-Harrison’s argument and assume that the hopping energy $t \propto r^{-\beta}$.

Between the hopping parameter $t_{ij,\mu\nu}$, we assume $t'_{ij,\mu\nu} = t_{ij,\mu\nu}(1 - \beta_{\mu\nu} \delta_{j} \cdot \delta_{j})\beta_{\mu\nu}$. This approximation is also the case for graphene under strain because the angle between $p_z$ orbitals does not change. The angular dependence becomes more important when deformations, such as nanobubbles and kirigami patterns, create large curvature (bending) and phosphorene. In buckled lead chalcogenides, however, the relevant hopping terms for the Rashba dispersion depend on the buckling angle even in the simple case of biaxial strains. Thus we will include this angular dependence, and we will show that this is important to capture the changes in Rashba coupling with uniaxial strain.

Let the unstrained vector connecting an atom $A$ and its neighbor be defined as $\delta_j = (x,y,z)$ and the equilibrium distance $r = d$. Here we show the derivation for $t'_{p_x,p_z}$, while the others can be found by following the same procedure. We assume $\Delta(r') = \Delta_0 (r'/d)^\beta$ and we expect $\beta \approx 3$. In Cartesian coordinates the strained hopping is given by $t'_{p_x,p_z}(x',y',z') = \frac{x'y'z'}{r'^2} \Delta_0 (\frac{r'}{d})^\beta$, and by Taylor expansion we obtain,

$$
\delta t_{ij,p_x,p_z}(x',y',z') \simeq -t_{ij,p_x,p_z}(x,y,z) \left( \frac{(2 + \beta) - (r/x)^2}{r^2} x \cdot (x' - x) - \frac{(2 + \beta)}{r^2} y \cdot (y' - y) - \left[ (2 + \beta) - (r/z)^2 \right] \frac{1}{r^2} z \cdot (z' - z) \right) \cdot (2)
$$

Within the strain approximation $x' - x = \hat{x} \cdot \hat{\delta}_j$. If we alter only the bond distance while keeping the angle constant, we will get the same expression as above when angular effects are assumed to be negligible.

The interlattice-spinless Hamiltonian in reciprocal space can be written as
where \((ij)\) is the sum over nearest neighbor pairs and \(\Delta_j = R_j - R_i\). The first term \(H_0\) is the unstrained Hamiltonian, \(H^{(1)}\) is the correction due to lattice deformation, and \(H^{(2)}\) is the correction from the altered hopping parameter due to changes in both the interatomic distance and angle between orbitals.

IV. HOMOGENEOUS ISOlropic STRAINS

We start with a simple deformation with no shear \(\hat{\epsilon} = \begin{pmatrix} \epsilon_{xx} & 0 & 0 \\ 0 & \epsilon_{yy} & 0 \\ 0 & 0 & \epsilon_{zz} \end{pmatrix}\). We will focus on the matrix elements that are relevant to the conduction band, such as \(|A|/|1,0\) and \(|B|/|1,1\). In the angular momentum basis, the correction from \(H^{(1)}\) and \(H^{(2)}\) at \(M\) is given by

\[
A(1,0)H^{(1)}(1,1)B = a_0 \sqrt{2} a_0 \Delta_0 \gamma_0 \left[ \epsilon_{xx} \pi/a_0 + q_x \epsilon_{xx} - i \epsilon_{yy} \pi/a_0 - i q_y \epsilon_{yy} \right]
\]

\[
A(1,0)H^{(2)}(1,1)B = -a_0 \sqrt{2} a_0 \Delta_0 \alpha_0 \gamma_0 \left[ \epsilon_{xx} f_1 \epsilon_{yy} + f_2 \epsilon_{zz} q_x - (f_1 \epsilon_{xx} + \epsilon_{yy} + f_2 \epsilon_{zz}) q_y \right]
\]

where \(\epsilon_{ij} = \frac{i}{2} \left( \frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right)\), \(f_1 = 1 - \frac{1}{a_0^2 (2 + \beta)}\) and \(f_2 = \frac{\gamma_0}{a_0^2} - \frac{1}{a_0^2 (2 + \beta)}\). Note that \(\alpha_0, \alpha_0, \beta_0, \gamma_0, \Delta_0\) are the unstrained geometrical and hopping parameters. \(H^{(1)}\) is independent of the \(z\) direction strains (e.g. \(\epsilon_{zz}\)) because the lattice vector \(\mathbf{R}\) and \(\mathbf{k}\) are two-dimensional. Because of the symmetry of \(M\), we found that the first correction at \(M\) due to bond alterations is first order in \(\epsilon\) and angular momentum. \(H^{(1)}\) is also independent of \(q\), and \(\epsilon\).

To obtain \(\beta\) we will consider an isotropic strain \(\epsilon \cdot 1_{3 \times 3}\). Notice that the change in low-energy Hamiltonian of Eq. 1 due to \(H^{(1)}\) and \(H^{(2)}\) at \(M\) can be written as gauge potentials,

\[
H_{\text{eff}} = -i\lambda_0 \begin{pmatrix} 0 & 0 \\ \langle q_x + i q_y \rangle + A_1 + A_2 \end{pmatrix} \begin{pmatrix} 0 \\ \langle q_x - i q_y \rangle + A_1 + A_2 \end{pmatrix}.
\]

where \(A_1 = \left( \frac{\epsilon \pi}{a_0} + \frac{\epsilon q_x}{a_0} \right)\) and \(A_2 = -\beta \left( \frac{-i \epsilon q_y}{a_0} \right)\), where we have used \(2 \alpha_0^2 + \gamma_0^2 = 1\) to simplify \(A_1, A_2\) and \(\lambda_0\) is the unstrained Rashba parameter.

\(A_2\) and the second term of \(A_1\) are proportional to \(q\). This modifies the strength of Rashba parameter \(\lambda\), \(1 \simeq (1 - \beta)\). This alteration in the Rashba term is similar to the modification of Fermi velocity in graphene.\textsuperscript{30–32}

We next present our DFT results to validate our TB predictions. Details of DFT calculations and the unstrained geometrical parameters of buckled PbS, PbSe, and PbTe can be found in Appendix A 1. Strains are applied to the relaxed buckled phase. In order to find the effects that come from changes in bond distance only, we deformed the monolayer in the DFT simulations by changing the bond distance while keeping the angle constant. The lattice vectors and atomic positions are not relaxed under this deformation. The Rashba parameters \(\lambda\) are obtained by taking the derivative of the energy dispersion in the vicinity of the M point, \(|q| < 0.1 \pi/a_0\). Under isotropic deformations, we found that \(\lambda\) at \(M\) decreases with increasing strain (weakening of the hopping interaction), as expected from Eq. 5, shown in fig. 1(c)-(e). A direct comparison between DFT results and TB with strain-included allows us to extract \(\beta\). By fitting DFT data points to a straight line, we obtained \(\beta = 3.25, 3.20, 2.97\) for PbS, PbSe, and PbTe, respectively (fig. 1(e)). We see that the value of \(\beta\) would be different if the lattice deformation correction was not included.
As we stretch the lattice, the Brillouin zone (BZ) will shrink, and the corner of the BZ (M point) will shift as \((\frac{\pi}{a_0}, \frac{\pi}{a_0}) \to (\frac{\pi}{a_0(1+\epsilon)}, \frac{\pi}{a_0(1+\epsilon)}) \approx (\frac{\pi}{a_0(1-\epsilon)}, \frac{\pi}{a_0(1-\epsilon)})\), where \(a_0\) is the undeformed lattice constant. For positive strains, the M point shifts towards the \(\Gamma\) point (relative to the undeformed BZ), shown in fig. 1(b). In our modified TB model, the M point is displaced due to the first term of the lattice deformation correction \(\mathbf{A}_1\) (see Eq. 5). The momentum shifts due to lattice deformations are also found in graphene. The changes in Rashba dispersion and its locations due to strains are illustrated in fig. 2.

To show the momentum shifts relative to the undeformed (reference) state, we plot the energy spin-splitting at the conduction band of PbS obtained from the DFT results as a function of \(k_x, k_y\), shown in fig. 1(f) and (g). Note that momenta are in units of \(\pi/a_0\). Originally the M points are located at \(|k_{x,y}| = \pi/a_0\) and are shifted closer to \(\Gamma\) \((|k'_{x,y}| \approx 0.9\pi/a_0)\) when an isotropic strain of \(\epsilon = 0.10\) is applied. The momentum shift is linear with strains \(\mathbf{k} \cdot \mathbf{\epsilon}\), consistent with several previous works.

This Rashba-point shift due to strains is equivalent to applying in-plane-magnetic fields \(\mathbf{B}_{\text{ex}}\) to the system,

\[
H = \lambda_0 \left[ \mathbf{q} \cdot \mathbf{\epsilon} \right] \times \sigma \cdot \mathbf{\epsilon} + m_\perp \sigma_z B_\perp + m_\parallel \sigma \parallel \mathbf{\epsilon}
\]

where \(m_\perp = -\mu_B(c_2^2 - 2c_3^2)\), \(m_\parallel = -\mu_Bc_1(c_2^2 + c_1 + c_0)\), and \(\mu_B\) is the Bohr magneton. For completeness the derivation of Eq. 6 is included in Appendix D. As an illustration, we can choose an external field of \(\mathbf{A}_{\text{ex}} = (0, 0, B_x y - B_y x)\), upon which the in-plane magnetic field is given by \(\mathbf{B}_{\text{ex}} = \nabla \times \mathbf{A}_{\text{ex}} = (B_x, B_y, 0)\). Since the Bohr magneton is small, in order to get a similar effect of 2% strain using magnetic fields, one has to apply external magnetic fields with an approximate strength of \(|B_{\text{ex}}| \sim \sqrt{300.02 r_0 a_0 m_\parallel} \approx 600\) Tesla (by Eq. 5 and Eq 6).

V. ELECTRIC POLARIZATION AND RASHBA FIELD

Proposals have been made to change the spin texture (i.e. sign of \(\lambda\)) by changing the electric polarization. Rinaldi et al. found that the spin-texture in FERSC GeTe films indeed depends on the locations of the atoms on the surface, which dictate the direction of the electric polarization. In DFT simulations of SnTe thin films, which have a structure similar to PbX, it also has been shown that near the vacuum one of the atomic species buckles outward while the other species buckles inward. While the proportionality between Rashba parameter and spontaneous electric polarization is well known, it will be useful to understand this mechanism in PbX from a microscopic view, where the changes in Rashba parameters can be understood in terms of interactions between atoms and the external applied strains. We will show that our strain-dependent TB model captures how the out-of-plane strain, which is proportional to the out-of-plane polarization, modifies the Rashba fields.

By the modern theory of polarization, the electric polarization is given by \(\mathbf{P} = \frac{1}{V} \sum_i q_{i\text{ion}} \mathbf{R}_i - \frac{2e c}{(2\pi)^3} \sum_{n\tau} \int_{BZ} d^3k \mathbf{e}^{i\mathbf{k} \cdot \mathbf{R}} \left\langle \Psi_{n\mathbf{k}} \frac{\partial \Psi_{n\mathbf{k}}}{\partial \mathbf{k}} \right\rangle\), where \(q_{i\text{ion}}\) is the ionic charge plus the core electrons, \(\mathbf{R}_i\) is the position of ions, \(V\) is the unit cell volume, \(e\) is the elementary charge, \(n\) is the valence band index, \(\mathbf{k}\) is the wave vector, and \(\Psi_{n\mathbf{k}}\) is the electronic wave function. The first term is the contribution from core electrons and ions, and the second term is the electronic contribution defined as the adiabatic flow of current, which can be calculated from the Berry phase (BP). The spontaneous polarization is calculated by taking the difference between the polarization of the polar (buckled) state and the non-polar (reference) state, \(\Delta \mathbf{P} = \mathbf{P}_{\text{polar}} - \mathbf{P}_{\text{non-polar}}\). We estimate the thickness to be 0.5 nm in order to compare the polarizations to typical bulk ferroelectrics. Details can be found in Appendix B. In the DFT simulations we distort the ions in the \(z\) direction while keeping the in-plane lattice vectors fixed at the relaxed buckled values. We report only the spontaneous polarizations of PbS and PbSe, as PbTe is metallic. A modified Berry phase calculation is needed to evaluate polarization of ferroelectric metals; however this is beyond the scope of our present study.

From the DFT results we found that the core electronic plus ionic and the electronic contribution (BP) are proportional to the distance between Pb and X (X=S, Se) in the \(z\) direction (plotted in Appendix B). This gives a proportionality between \(\Delta \mathbf{P}_{zz}\) and \(\epsilon_{zz}\), as shown in fig. 3(a). Compressing the monolayer in the \(z\) with strain \(\epsilon_{zz} < 0\) results in a decrease in \(\lambda\), shown in fig. 3(b). This is op-

FIG. 3. (a) Out-of-plane polarization \(\Delta \mathbf{P}_{zz}\) as a function of out-of-plane strain \(\epsilon_{zz}\). (b) Linear relationship between \(\lambda\) and \(\epsilon_{zz}\) which is consistent with TB predictions. (c) Rashba parameter \(\lambda\) as a function of \(\Delta \mathbf{P}_{zz}\). All data points are obtained from the DFT calculations.
poste to the case of isotropic deformation (see fig. 1(e)). This result is consistent with TB predictions. In the previous discussion, we found that increasing bond distance ($\epsilon > 0$) generally weakens the hopping interaction and thus decreases $\lambda$. Using relaxed geometrical parameters (i.e. buckling angle $\theta_0$) and from Eq. 4, $\lambda$ is expected to decrease with compressive strain in the $\hat{z}$ as $f_z$ is negative. We also want to note that there is no gauge-field $A_\alpha$ since $k$ is two-dimensional, and thus $M$ is not shifted. The changes in Rashba dispersion and its locations due to out-of-plane strains are illustrated in fig. 2(b). Notice that not including the angular dependence in the hopping correction will not capture this effect. The inclusion of the angular dependence is particularly important for the PbX monolayer due to its buckled nature. Overall, this suggests that the out-of-plane internal electric polarization acts as an in-plane gauge field in the low-energy Hamiltonian. Assuming small strains, we found that $\lambda \propto |\overline{P}_z|$. This result is important as it establishes a direct relationship between the Rashba field and the out-of-plane polarization which is also proportional to the out-of-plane strain $\epsilon_z$. Recently, several works have also studied strain-induced piezoelectricity in boron nitride$^{10}$ and TMDCs$^{41}$. Several experimental works use out-of-plane magnetic fields (parallel to the polar axis of Rashba materials) to measure the Rashba parameter as the Landau level spectrum changes with the strength of the Rashba parameter$^{14,42}$. One could also use this experimental approach to detect variations in the Rashba parameter in PbX due to out-of-plane strains.

VI. CONCLUSIONS

We have developed a TB model where the electronic changes in PbX can be described within continuum mechanics. We found the scaling exponent that modifies the hopping parameter to be $\beta \approx 3$. In the low-energy Hamiltonian, the effect of strains can be described as gauge fields, which are equivalent to, by minimal coupling, application of an in-plane magnetic field. Our theory describes how the location of the Rashba point and the strength of the Rashba field can be engineered by applying strains. The out-of-plane strain in particular is directly related to the out-of-plane polarization. Within this framework we are able to understand the connection between the Rashba and ferroelectricity.

Our strain-dependent TB model should be applicable for calculating the effects of inhomogeneous strain on the spatially-resolved Rashba fields over a large region, whereas this calculation would not be feasible within a reasonable time using a DFT approach. Employing classical atomistic simulations (e.g. molecular dynamics) together with strain-dependent TB will be an efficient tool for studying larger and more realistic systems with strain modulation due to substrates, indentors$^{12,13,43}$ or geometrical cuts$^{28,44}$. This will open possibilities of using lead chalcogenides for strain and electric-controlled spintronic devices.

ACKNOWLEDGMENTS

P.Z.H. developed the theory, wrote the paper, and performed the DFT calculations. A.S.R. contributed to the analytical work. H.S.P., D.K.C., and A.C.H.N. supervised the research. We thank Vitor M. Pereira for useful comments and discussions. P.Z.H., H.S.P., and D.K.C. acknowledge support by the Boston University Materials Science and Engineering Innovation Grants. P.Z.H, H.S.P., and D.K.C are grateful for computing resources provided by theBostonUniversity Shared Computing Cluster.

Appendix A: Methods

1. Computational Details

To validate our tight-binding predictions we performed density functional theory (DFT) calculations implemented in the QUANTUM ESPRESSO package. We employed projector augmented-wave (PAW) type pseudopotentials with Perdew-Burke-Ernzerhof (PBE) within the generalized gradient approximation (GGA) for the exchange and correlation functional with. The Kohn-Sham orbitals were expanded in a plane-wave basis with a cutoff energy of 100 Ry and a charge density cutoff of 200 Ry. The cutoff was chosen following the suggested minimum cutoff in the pseudopotential file. A k-point grid sampling was generated using the Monkhorst-Pack scheme with 16×16×1 points. A vacuum of 20 Å was used. The relaxed structures of PbS, PbSe, and PbTe were obtained by relaxing the ionic positions and the lattice vectors. A convergence threshold on total energy of 10−5 eV and a convergence threshold on forces of 0.005 eV/Å were chosen. Lattice vectors are relaxed until the stress is less than 0.01 GPa. Our first-principles calculations show that the buckled phase of the PbX monolayer is more stable than the centrosymmetric planar phase, consistent with other DFT studies. Detailed discussions on the bistable nature, ferroelectric properties and orbital-spin texture properties of lead chalcogenides can be found in our previous paper. In the current work, the deformations (atomic distortions) are applied to the optimized buckled structure. We used a finer grid for band structure calculations
with the spin-orbit interaction included. We have tried several large numbers of \( k \) points and found that a grid of 100 \( k \) points between two symmetry points (e.g between \( X \) and \( M \)) is enough to obtain the Rashba parameter \( \lambda \) at the \( M \) point\(^8\). A regular grid of 40\times40\times1 was used for the surface plot of the energy spin splitting.

Here we tabulate the optimized (relaxed) geometrical parameters of buckled \( \text{PbX} \) (\( X=\text{S}, \text{Se}, \) and \( \text{Te} \)) monolayers in table I. The Rashba parameters \( \lambda \) are obtained by taking the derivative of energy dispersion near the \( M \) point. The orbital coefficients are obtained by projecting the wave functions into the atomic orbital basis. The unstrained values of \( \lambda \) and \( \Delta \) are tabulated in table II. From the table it can be seen that the wave functions are mostly composed of in-plane and out-of-plane of \( p \) orbitals of \( \text{Pb} \) and an in-plane orbital of the chalcogen \( \text{X} \) (\( X=\text{S}, \text{Se}, \text{Te} \)).

| Table I. Relaxed lattice constant \( a \), buckling angle \( \theta \), buckling height \( d_z \), nearest-neighbor bond distance \( d \). |
|---|---|---|---|
| \( \text{PbS} \) | 3.74 | 21.6 | 1.04 | 2.84 |
| \( \text{PbSe} \) | 3.82 | 24.3 | 1.22 | 2.96 |
| \( \text{PbTe} \) | 4.01 | 26.3 | 1.40 | 3.16 |

| Table II. Rashba parameters \( \lambda \), projected wave functions coefficients \( |c_1|^2 \), \( |c_1|^2 \), \( |c_2|^2 \) obtained from DFT and \( \Delta \). |
|---|---|---|---|
| \( \text{PbS} \) | 0.305 | 0.534 | 0.115 | 3.40 | 5.36 |
| \( \text{PbSe} \) | 0.272 | 0.549 | 0.137 | 3.37 | 4.28 |
| \( \text{PbTe} \) | 0.286 | 0.522 | 0.130 | 3.18 | 3.83 |

Appendix B: Electric polarization

We used the modern theory of polarization\(^38\) to calculate the spontaneous polarization implemented in the QUANTUM ESPRESSO package\(^45\). The electric polarization is calculated via Berry phase calculation\(^38\), which is given by

\[
\vec{P} = \frac{1}{V} \sum_{\tau} q^\text{ion}_\tau \vec{R}_\tau - \frac{2ie}{(2\pi)^3} \sum_{n} \int_{BZ} d^3k e^{-ik\vec{R}} \left\langle \Psi_{nk} \left| \frac{\partial \Psi_{nk}}{\partial \vec{k}} \right. \right|,
\]

where \( q^\text{ion}_\tau \) is the ionic charge plus the core electrons, \( \vec{R}_\tau \) is the position of ions, \( V \) is the unit cell volume, \( e \) is the elementary charge, \( n \) is the valence band index, \( \vec{k} \) is the wave vector, and \( \Psi_{nk} \) is the electronic wave function. The first term is the contribution from core electrons and ions, and the second term is the electronic contribution defined as the adiabatic flow of current which can be calculated from the Berry connection\(^38\).

The spontaneous polarization is calculated by taking the difference between the polarization of the polar (buckled) state and the non-polar (reference) state,

\[
\Delta \vec{P} = \vec{P}_\text{polar} - \vec{P}_\text{non-polar}.
\]

To find the polarization at different heights, we change the out-of-plane distance between the \( \text{Pb} \) and \( \text{X} \) (\( X=\text{S}, \text{Se} \)) atom while keeping the in-plane lattice vectors fixed at the optimized buckled values. It is a common practice to use a value on the order of the bulk lattice constant (0.5–1 nm) to estimate the monolayer thickness in order to compare the polarization of monolayers to the typical bulk ferroelectrics\(^49–51\). In this current work we estimate the thickness to be 0.5 nm. In QUANTUM ESPRESSO, spontaneous polarization with spin-orbit included can be calculated using norm conserving pseudopotentials. A difference of 0.03 \( \mu \text{C/cm}^2 \) is found when spin-orbit interaction is included. Thus, to save computational time we only report spontaneous polarization without inclusion of the spin-orbit interaction. This small difference has also been reported previously\(^35,52\). In figure. 4 we plot the polarization from the ionic plus core electron contribution, and the electronic contribution, from the Berry phase calculation, scaled by their values at zero strain as a function of distance between the \( \text{Pb} \) and \( \text{S} \) atom in the \( z \) direction.

Appendix C: Tight binding

The lead chalcogenide monolayer has two atoms per unit cell \((A,B)\). Based on density functional theories, the relevant orbitals near the valence and conduction bands are \( s \) and \( p \) orbitals. The wave function of sublattice \( A \) then can be written as

\[
\psi^A(r) = \frac{1}{\sqrt{N}} \sum_{\vec{k},\mu} e^{i\vec{k}\vec{r}} a_{\mu,\vec{k}} \phi_{\mu}(\vec{r} - \vec{R}),
\]

where \( \vec{R} \) is the lattice vector, \( \vec{k} \) is a wave vector, \( \mu \) is the basis wave function \([s,p_x,p_y,p_z]\). Including only nearest
neighbor hopping the spinless Hamiltonian can be written as

\[ H_{\text{orb}} = \sum_{i,j} \sum_{\mu,\nu} [t_{ij,\mu\nu} c_{i,\mu}^\dagger c_{j,\nu} + h.c] + \sum_{i,j} \sum_{\mu,\nu} E_{\mu\nu} c_{i,\mu}^\dagger c_{i,\nu}, \]  

(C2)

where \((i,j)\) runs over the onsite cell and the nearest neighboring cells. \(c_{i,\mu}^\dagger\) creates an electron in the unit cell \(i\) with atomic orbital \(\mu\). We can write this more compactly as

\[ H_{\text{orb}} = \begin{pmatrix} H_{AA} & H_{AB} \\ H_{AB}^\dagger & H_{BB} \end{pmatrix}, \]  

(C3)

where \(H_{AA}\) (the onsite term) is given by

\[ H_{AA} = \begin{pmatrix} E_A^s & 0 & 0 & 0 \\ 0 & E_A^{p\sigma} & 0 & 0 \\ 0 & 0 & E_B^{p\sigma} & 0 \\ 0 & 0 & 0 & E_A^{p\sigma} \end{pmatrix}. \]  

(C4)

To write down the hopping matrix, we use the following Slater-Koster matrix elements for the orbitals of neighboring atoms\(^20\):

\[
\begin{align*}
\text{s-s} : & \ V_{s\sigma,s\sigma}, \\
\text{s-p} : & \ V_{s\sigma,p\sigma} \hat{\mathbf{d}} \cdot \hat{\mathbf{d}}_j, \\
\text{p-p} : & \ (\hat{\mathbf{d}}_i \cdot \hat{\mathbf{d}}) \left( V_{pp\sigma} - V_{pp\pi} \right). 
\end{align*}
\]

(C5)

Here, \(\hat{\mathbf{d}}_i\) is the orientation of the \(i\)th orbital and \(\hat{\mathbf{d}}\) is the unit vector pointing from atom 1 to atom 2. If we include up to first nearest neighbors only we can write the inter-lattice hopping matrix \(H_{AB} \equiv K\) as

\[
K = \Theta_T \begin{pmatrix} V_{s\sigma,s\sigma} & 0 & \alpha^2 \Delta & 0 & -\gamma V_{p\pi}^{(1)} & 0 \\ 0 & V_{p\pi} + \alpha^2 \Delta & 0 & 0 & 0 & 0 \\ \gamma V_{s\sigma p\sigma}^{(2)} & 0 & V_{p\pi} + \alpha^2 \Delta & 0 & 0 & 0 \\ 0 & 0 & 0 & V_{p\pi} + \alpha^2 \Delta & 0 & 0 \\ 0 & 0 & -i \gamma \Delta & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix} + 4 \alpha^2 \Delta \Theta_M \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix} +
\]

\[+ 4 \alpha \Theta_X \begin{pmatrix} 0 & 0 & i V_{p\sigma s\sigma}^{(1)} & 0 & 0 & 0 \\ 0 & 0 & 0 & -i \gamma \Delta & 0 & 0 \\ -i V_{p\sigma s\sigma}^{(2)} & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix} + 4 \alpha \Theta_Y \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ -i V_{p\sigma s\sigma}^{(2)} & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}, \]  

(C6)

where \(\Theta_T,M,X,Y = \left[ \cos \frac{k_u a}{2} \cos \frac{k_u a}{2}, \sin \frac{k_u a}{2} \sin \frac{k_u a}{2}, \sin \frac{k_u a}{2} \cos \frac{k_u a}{2}, \sin \frac{k_u a}{2} \cos \frac{k_u a}{2} \right]\).

The momentum \(\pi/a \leq k_x/y \leq \pi/a\) and \(\gamma = \sin \theta\). To keep the expression more compact, we have introduced \(\Delta = V_{pp\sigma} - V_{pp\pi}\). In addition, since the \(A\) and \(B\) species are not necessarily the same, we have two quantities of the \(V_{s\sigma p\sigma}\) form.

While it is convenient to use \(s\) and \(p\) orbitals to write down the hopping matrix, since we are interested in including SOI in our model, it is helpful to go to a basis which is more natural for the angular momentum opera-
\[
K = \Theta_{\Gamma} \begin{pmatrix}
V_{ss} & 0 & 0 & -\gamma V_{sp}^{(1)} \\
0 & V_{pp} + \alpha^2 \Delta & 0 & 0 \\
0 & 0 & V_{pp} + \alpha^2 \Delta & 0 \\
\gamma V_{sp}^{(2)} & 0 & 0 & V_{pp} + \gamma^2 \Delta
\end{pmatrix} + 4\alpha^2 \Delta \Theta_M \begin{pmatrix}
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0
\end{pmatrix} + 2\sqrt{2}\alpha \Theta_X \begin{pmatrix}
0 & 0 & 0 & 0 \\
0 & -iV_{sp}^{(1)} & V_{sp}^{(1)} & 0 \\
V_{sp}^{(2)} & -iV_{sp}^{(2)} & 0 & 0 \\
iV_{sp}^{(2)} & -iV_{sp}^{(2)} & 0 & 0
\end{pmatrix} + 2\sqrt{2}\alpha \Theta_Y \begin{pmatrix}
0 & V_{sp}^{(1)} & V_{sp}^{(1)} & 0 \\
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
0 & -\gamma & -\gamma & 0
\end{pmatrix}.
\]

(C8)

From here we write \( H = U H_{\text{orb}} U^{-1} \), where \( U \) is a matrix projector from the orbital basis to the angular momentum basis.

To include the SOI, we use the standard form describing the spin-orbit coupling arising from the interaction with the nucleus:

\[
H_{\text{SOI}} = T_X \left( L_+ \otimes s_- + L_- \otimes s_+ + L_z \otimes s_z \right),
\]

(C9)

where \( X \) is either Pb or X (X=Se, Te). The last term modifies the diagonal elements of the self-energy for \( |1, \pm 1\rangle \) by adding (subtracting) \( T_X/2 \) if \( L_z \) and \( s_z \) point in the same (opposite) direction. The first term couples \( |1,1\rangle \otimes |\downarrow\rangle \) with \( |1,0\rangle \otimes |\uparrow\rangle \) and \( |1,-1\rangle \otimes |\uparrow\rangle \) with \( |1,0\rangle \otimes |\downarrow\rangle \) with the coupling strength \( T_X/\sqrt{2} \).

The total Hamiltonian can then be written as

\[
H_{\text{tot}} = H \otimes 1_{2 \times 2} + H_{\text{SOI}}
\]

(C10)

1. \( M \) Point

We first look around the \( M \) point \( k_x = k_y = \pi/a \). To the leading order in \( q \), the hopping matrix \( K \) is given by,

\[
\begin{pmatrix}
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0
\end{pmatrix}
+ 4\alpha^2 \Delta \begin{pmatrix}
0 & 0 & 0 & -\gamma V_{sp}^{(1)} \\
0 & 0 & 0 & V_{sp}^{(1)} + \alpha^2 \Delta \\
0 & 0 & 0 & V_{sp}^{(1)} + \gamma^2 \Delta \\
0 & 0 & 0 & 0
\end{pmatrix} + 2\sqrt{2}\alpha \Theta_X \begin{pmatrix}
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0
\end{pmatrix} + 2\sqrt{2}\alpha \Theta_Y \begin{pmatrix}
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0
\end{pmatrix}.
\]

Several uncoupled blocks with the corresponding bases:

\[
H_{s}^{m,\pm} = E_{m}^{p} : |0,0\rangle \otimes |\pm \rangle \otimes |m\rangle,
\]

\[
H_{p}^{m,\pm} = E_{m}^{p} : |m\rangle \otimes |1,\pm 1\rangle \otimes |\mp\rangle \otimes |\mp\rangle
\]

where \( m \neq n \) labels the sublattices and the middle \( |\pm\rangle \) ket denotes the spin state. Using the direct sum notation, we can write down the total Hamiltonian as \( H = H_{A}^{A} + H_{B}^{B} + H_{A}^{C} - H_{B}^{C} + H_{A}^{D} - H_{B}^{D} + H_{A}^{B} - H_{B}^{B} \).

From \( H_{s} \), we see that for a given \( m \), the eigenstates are spin-degenerate. The degeneracy becomes four-fold if the atoms of sublattices \( A \) and \( B \) are the same, leading to \( E_{A}^{p} = E_{B}^{p} \). Equation (C11) shows that at finite \( q \) there is no coupling between the degenerate \( |0,0\rangle \) states that is linear in momentum. This means that the bands composed of \( s \) orbitals have local extrema at the \( M \) point.

Next, we turn to \( H_{p} \) from Eq. (C12). Just like for \( H_{s} \), the bands are doubly or four-fold degenerate depending on whether the sublattices are composed of the same atomic species. Without making assumptions about the lattice composition, the general form of the degenerate states is

\[
|\Psi_{m}^{\pm}\rangle = c_{0}|m\rangle \otimes |1,\pm 1\rangle \otimes |\mp\rangle + c_{1}|m\rangle \otimes |1,0\rangle \otimes |\pm\rangle \pm i c_{2}|m\rangle \otimes |1,\mp 1\rangle \otimes |\mp\rangle,
\]

with \( c_{0}, c_{1}, \) and \( c_{2} \) real. At finite \( q \),

\[
\langle m_{n}|\Psi_{m}^{+}|m\rangle = -a \sin 2\theta c_{1} c_{2} (\Delta i q e^{-i\phi}) \epsilon_{mn},
\]

(C14)

where \( \epsilon_{AB} = -\epsilon_{BA} = 1 \) is the two-dimensional Levi-Civita symbol. This coupling between the degenerate states leads to an effective Rashba-like Hamiltonian:

\[
H_{\text{eff}}^{mn} = a \sin 2\theta c_{1} c_{2} \Delta \epsilon_{mn} \left[(\mathbf{q} \times \mathbf{\sigma}) \cdot \mathbf{\tilde{z}}\right]:\left(|\Psi_{+}^{+}\rangle_{mn},|\Psi_{-}^{-}\rangle_{mn}\right).
\]

(C15)

or in the matrix form

\[
H_{\text{eff}} = \begin{pmatrix}
0 & -i\lambda(q_{x} - i q_{y}) \\
i\lambda(q_{x} + i q_{y}) & 0
\end{pmatrix},
\]

(C16)
We use values of $c_0$, $c_1$, and $c_2$ obtained from DFT results. To give better physical pictures of these coefficients, we will solve the Hamiltonian Eq. C12. We treat the spin orbit interaction (SOI) as perturbations and we will assume that $T_m \gg T_n$, where $m$ is the index denoting Pb with strong SOI and $n$ denotes weak SOI of chalcogen atom. Focusing on $H_p^{mn,+}$, Eq. C12 becomes

$$H_p^{mn,+} = \begin{pmatrix} E_p^m & 0 & -4i\alpha^2\Delta \\ 0 & E_p^n & 0 \\ 4i\alpha^2\Delta & 0 & E_p^n \end{pmatrix} : \begin{pmatrix} \langle m| \otimes |1,1\rangle \otimes |-\rangle \\ \langle m| \otimes |1,0\rangle \otimes |+\rangle \\ \langle n| \otimes |1,-1\rangle \otimes |-\rangle \end{pmatrix}.$$  

and the perturbation

$$\delta H_p^{mn,+} = \begin{pmatrix} -\frac{T_m}{\sqrt{2}} & \frac{T_m}{\sqrt{2}} & 0 \\ \frac{T_m}{\sqrt{2}} & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} : \begin{pmatrix} \langle m| \otimes |1,1\rangle \otimes |-\rangle \\ \langle m| \otimes |1,0\rangle \otimes |+\rangle \\ \langle n| \otimes |1,-1\rangle \otimes |-\rangle \end{pmatrix}.$$  

We first solved Eq. C17 to find the eigenvalues and eigenvectors and used first order perturbation theory to obtain the corrections to the eigenvectors. Using MATHEMATICA, we found to the first order in $T_m$ that

$$|c_1c_2| \approx \frac{T_m(E_p^m \mp E_p^n) + \sqrt{(E_p^m - E_p^n)^2 + 64\alpha^4\Delta^2}}{8\sqrt{2}\alpha^2\Delta(E_p^m - E_p^n) + \sqrt{(E_p^m - E_p^n)^2 + 64\alpha^4\Delta^2}}.$$  

Recall that we defined Rashba parameter $\lambda \equiv \langle \sin 2\theta \Delta |c_1c_2 \rangle$. From Eq. C19 we see that $|c_1c_2|$ weakly depends on strains. For this reason, in the main text we assumed $c_1$ and $c_2$ are constant and the corrections to $\lambda$ come mostly from $\Delta$ and $\theta$.

**Appendix D: Magnetic Field**

Let us now try to include external fields to the system. The magnetic field can be included via the Peierls substitution so that $q \rightarrow q - eA/c$, where $A$ is the vector potential. In addition, applying an external magnetic field leads to the interaction of the electron angular momentum with the field.

The total magnetic moment of an electron is given by

$$\mu = -\mu_B \frac{\mathbf{L} + 2\mathbf{S}}{\hbar},$$  

so that

$$\mathbf{B} \cdot \mu = -\mu_B B_x \left( \frac{L_x + L_y}{2} + S_x + S_z \right) + B_y \left( \frac{L_x - L_y}{2i} + S_x - S_z \right) + B_z (L_z + 2S_z).$$  

Setting $B = (B_\parallel \cos \tau, B_\parallel \sin \tau, B_\perp)$ gives

$$\mathbf{B} \cdot \mu = -\mu_B B_\parallel \cos \tau \left( \frac{L_x + L_y}{2} + S_x + S_z \right) - B_\parallel \sin \tau \left( \frac{L_x - L_y}{2i} + S_x - S_z \right) + B_\perp (L_z + 2S_z)$$

$$= -\mu_B \frac{B_\parallel \left( e^{-i\tau} \left( \frac{L_x}{2} + S_x \right) + e^{i\tau} \left( \frac{L_x}{2} + S_x \right) \right) + B_\perp (L_z + 2S_z)}{\hbar}. $$  

The first term $\propto B_\parallel$ introduces coupling between $|\Psi^+\rangle$ while the last term $\propto B_\perp$ modifies and breaks the symmetry between the degenerate states. Starting with last term, we get

$$\langle \Psi^+ | \mathbf{B} \cdot \mu | \Psi^+ \rangle = -\langle \Psi^- | \mathbf{B} \cdot \mu | \Psi^- \rangle = -\mu_B B_\perp \left( c_1^2 - 2c_2^2 \right).$$  

Next, we apply the first term onto $|\Psi^+\rangle$:

$$-\mu_B B_\parallel \left[ e^{-i\tau} \left( \frac{L_x}{2} + S_x \right) + e^{i\tau} \left( \frac{L_x}{2} + S_x \right) \right] (c_0|m\rangle \otimes |1,1\rangle \otimes |-\rangle + c_1|m\rangle \otimes |1,0\rangle \otimes |+\rangle + ic_2|n\rangle \otimes |1,-1\rangle \otimes |-\rangle)$$

$$= -\mu_B B_\parallel \left[ e^{-i\tau} c_0|m\rangle|1,1\rangle|+\rangle + e^{i\tau} \frac{c_0}{\sqrt{2}} |m\rangle|1,0\rangle|-\rangle + e^{-i\tau} \frac{c_1}{\sqrt{2}} |m\rangle|1,1\rangle|+\rangle \right]$$

$$+ e^{i\tau} \frac{c_1}{\sqrt{2}} |m\rangle|1,1\rangle|-\rangle + e^{i\tau} c_1|m\rangle|1,0\rangle|-\rangle + e^{-i\tau} \frac{c_2}{\sqrt{2}} |n\rangle|1,0\rangle|-\rangle + e^{i\tau} ic_2|n\rangle|1,1\rangle|+\rangle \right]$$

$$= -\mu_B B_\parallel \left[ e^{i\tau} \left( \frac{c_0}{\sqrt{2}} + c_1|m\rangle|1,0\rangle|-\rangle + e^{-i\tau} (c_0 + \frac{c_1}{\sqrt{2}})|m\rangle|1,1\rangle|+\rangle + c_1 e^{i\tau} c_1|m\rangle|1,1\rangle|+\rangle \right.$$  

$$+ e^{-i\tau} \frac{c_0}{\sqrt{2}} |n\rangle|1,0\rangle|-\rangle + e^{i\tau} ic_2|m\rangle|1,1\rangle|+\rangle \right)
Now, we apply \( \langle \Psi^- | \) onto Eq. (D5). We see that the states on \(| n \rangle \) drop out. The remaining states yield
\[
\langle \Psi^- | B \cdot \mu | \Psi^+ \rangle = -\mu B \| B \| e^{i\tau} \left[ c_1 \left( \frac{c_0}{\sqrt{2}} + c_1 + c_0 \right) \right].
\] (D6)

Thus, our general Hamiltonian becomes
\[
H = \lambda \left[ (q - \frac{cA}{c}) \times \sigma \right] \cdot \hat{z} + m_\perp \sigma_z B_\perp + m_\| B_\| \cdot \sigma_\|
\] (D7)
where \( m_\perp = -\mu B (c_1^2 - 2c_2^2) \) and \( m_\| = -\mu B \left[ c_1 \left( \frac{c_0}{\sqrt{2}} + c_1 + c_0 \right) \right] \).

Appendix E: In-Plane Field

If the field is in-plane, the Hamiltonian is given by
\[
H = \left( \begin{array}{cc} 0 & i\lambda ge^{i\phi} + B e^{-i\tau} \\ -i\lambda ge^{-i\phi} + B e^{i\tau} & 0 \end{array} \right) = \lambda \left( \begin{array}{cc} 0 & i\lambda g e^{i\phi} + B e^{-i\tau} \\ -i\lambda g e^{-i\phi} + B e^{i\tau} & 0 \end{array} \right),
\] (E1)
where we have defined \( B \equiv m_\| B_\| \). The eigenvalues become
\[
\mathcal{E} = \pm \lambda \sqrt{\left( q_x - \frac{B}{\lambda} \sin \tau \right)^2 + \left( q_y - \frac{B}{\lambda} \cos \tau \right)^2}.
\] (E2)

Applying an in-plane magnetic field shifts the cone in the Brillouin zone.

Let us take a closer look at the Hamiltonian:
\[
H = \lambda \left( \begin{array}{cc} 0 & i \left[ (q_x - \frac{B}{\lambda} \sin \tau) + i (q_y - \frac{B}{\lambda} \cos \tau) \right] \\ -i \left[ (q_x - \frac{B}{\lambda} \sin \tau) - i (q_y - \frac{B}{\lambda} \cos \tau) \right] & 0 \end{array} \right)
= \lambda \left( \begin{array}{cc} 0 & i \xi e^{i\xi} \\ -i \xi e^{-i\xi} & 0 \end{array} \right).
\] (E3)

The eigenstates are
\[
| I \rangle = \frac{| \Psi^+ \rangle + i e^{-i\xi} \langle \Psi^- |}{\sqrt{2}},
| II \rangle = \frac{| \Psi^+ \rangle - i e^{-i\xi} \langle \Psi^- |}{\sqrt{2}}.
\] (E4)

Now we can obtain the in-plane spin texture for the cones. First, it is easy to show that
\[
\langle \Psi^I | \sigma_{x/y} | \Psi^I \rangle = \langle \Psi^I | \sigma_{x/y} | \Psi^I \rangle = 0.
\] (E5)

Next,
\[
\langle \Psi^I | \sigma_x | \Psi^I \rangle = c_1^2 (| + | \sigma_x | - \rangle = c_1^2,
\langle \Psi^I | \sigma_y | \Psi^I \rangle = c_1^2 (| + | \sigma_y | - \rangle = -i c_1^2.
\] (E6)

This leads to
\[
\langle I | \sigma_x | I \rangle = \frac{-i e^{i\xi}}{2} c_1 + \frac{i e^{-i\xi}}{2} - c_2 = -c_1^2 \frac{e^{i\xi} - e^{-i\xi}}{2} = c_1^2 \sin \xi,
\langle I | \sigma_y | I \rangle = \frac{-i e^{i\xi}}{2} + \frac{i e^{-i\xi}}{2} = -c_1^2 e^{i\xi} - c_2 c_1^2 - c_2 \cos \xi,
\langle II | \sigma_x | II \rangle = \frac{i e^{i\xi}}{2} c_1^2 + \frac{-i e^{-i\xi}}{2} c_2 = c_1^2 \sin \xi,
\langle II | \sigma_y | II \rangle = i c_1^2 \frac{-i e^{i\xi}}{2} - i c_1^2 \frac{i e^{-i\xi}}{2} = c_1^2 \cos \xi.
\] (E7)
As a result, the spin texture becomes:

\[
\langle I | \hat{\sigma} | I \rangle = c_1^2 (\hat{x} \sin \xi - \hat{y} \cos \xi) \propto (\hat{x} p_y - \hat{y} p_x) ,
\]

\[
\langle II | \hat{\sigma} | II \rangle = -c_1^2 (\hat{x} \sin \xi - \hat{y} \cos \xi) \propto - (\hat{x} p_y - \hat{y} p_x) .
\] (E8)

Recall that

\[
p_x = q_x - \frac{\lambda}{\hbar v} \sin \tau ,
\]

\[
p_y = q_y - \frac{\lambda}{\hbar v} \cos \tau .
\] (E9)

This means that spin contours now revolve not around the \( q = 0 \) point but instead around a \( p = 0 \) point.
