Next-to-next-to-leading soft-gluon corrections for the
top quark cross section and transverse momentum
distribution

Abstract

I present results for top quark production in hadronic collisions at LHC and Tevatron
energies. The soft-gluon corrections to the differential cross section are resummed at next-
to-next-to-leading-logarithm (NNLL) accuracy via the two-loop soft anomalous dimension
matrices. Approximate next-to-next-to-leading-order (NNLO) differential and total cross
sections are calculated. Detailed theoretical predictions are shown for the $t\bar{t}$ cross section
and the top quark $p_T$ distribution at the Tevatron and the LHC.

1 Introduction

The top quark occupies a unique position in the list of elementary particles as the most massive
particle discovered to date. Its high mass suggests an important role for the top quark in the
physics of electroweak symmetry breaking. After a long period of searches, the discovery of the
top quark via top-antitop production in proton-antiproton collisions ($p\bar{p} \rightarrow t\bar{t}$) was announced
in 1995 by the CDF and D0 collaborations at the Fermilab Tevatron collider [1]. The $t\bar{t}$ cross
section has been measured with increasing precision at Run II of the Tevatron [2, 3] and there
has also been data for the transverse momentum, $p_T$, distribution of the top quark [4]. More
recently single top quark production was observed by D0 [5] and CDF [6]. Measurements of the
top quark mass have also been increasingly more precise [7]. The LHC is expected to observe a
very large number of top quark events and to bring top quark physics to a new energy frontier.
For reviews of top quark physics at the Tevatron and the LHC see Ref. [8] (experiment) and
Ref. [9] (theory).

The experimental measurements of the top quark cross section and $p_T$ distribution at the
Tevatron are currently in good agreement with theoretical predictions. However, as the experimental
errors continue to get smaller with time, precise theoretical calculations with smaller un-
certainties are required. Next-to-leading order (NLO) calculations of the QCD corrections have
been available for over two decades [10, 11] (electroweak corrections, which are much smaller
numerically, have also been calculated more recently [12]) but the associated uncertainty is
much bigger than current experimental errors. The inclusion of higher-order soft-gluon corrections
enhances the cross section and $p_T$ distribution and significantly reduces the theoretical
error [13, 14].

Until recently, the state of the art in theoretical predictions was approximate next-to-next-
to-leading order (NNLO) calculations based on next-to-leading-logarithm (NLL) resummation
of soft-gluon corrections for the differential cross section, supplemented with further subleading
These soft-gluon corrections are dominant not only near partonic threshold but also away from it. The accuracy at NLL was achieved by the calculation of the one-loop soft anomalous dimension matrices for the partonic channels in top quark production in Ref. [15].

To achieve next-to-next-to-leading-logarithm (NNLL) accuracy in the resummation one needs to calculate the soft anomalous dimensions at two loops. This is a much more difficult undertaking. For massless quark scattering, the two-loop soft anomalous dimension matrix was first calculated in Ref. [16]. Further work on soft and collinear singularities of dimensionally-regularized scattering amplitudes in massless gauge theories followed in Refs. [17, 18, 19, 20, 21]. More recently, a lot of work on massive two-loop soft anomalous dimensions has appeared in Refs. [22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32]. The presence of a mass for the top quark considerably complicates the calculation relative to the massless case.

Soft-gluon resummation is a consequence of factorization. The partonic cross section can be factorized into functions associated with the hard scattering, collinear and soft-gluon emission from the external partons, and noncollinear soft-gluon emission that depends on the color structure of the process [15]. The renormalization group evolution of these functions results in expressions for the resummed cross section. The resummation formalism followed here has already been presented and reviewed in numerous papers over a period of more than a decade (see Refs. [13, 15, 28, 29, 33, 34, 35] and references therein) so we will not repeat the derivation of resummation and we will not repeat explicit expressions in this paper except for new two-loop results in Section 2. Resummation is performed in Mellin moment space: we define a kinematical variable \( s_4 \) that measures distance from partonic threshold, and then \( \tilde{N} \) is the moment variable conjugate to \( s_4 \). For \( t\bar{t} \) production the resummed partonic cross section in moment space is given by

\[
\hat{\sigma}^{res}(N) = \exp \left[ \sum_{i=a,b} E_i(N_i) \right] \exp \left[ 2 \sum_{i=a,b} \int_{\mu_F}^{\sqrt{s}} \frac{d\mu}{\mu} \gamma_{i/i} \left( \tilde{N}_i, \alpha_s(\mu) \right) \right] \text{Tr} \left\{ H_{ab} \left( \alpha_s(\sqrt{s}) \right) \right\} 
\]

\[
\times \exp \left[ \int_{\sqrt{s}}^{\sqrt{s}/\tilde{N}'} \frac{d\mu}{\mu} \Gamma_{S_{ab}} \left( \alpha_s(\mu) \right) \right] S_{ab} \left( \alpha_s(\sqrt{s}/\tilde{N}') \right) \exp \left[ \int_{\sqrt{s}}^{\sqrt{s}/\tilde{N}'} \frac{d\mu}{\mu} \Gamma_{S_{ab}} \left( \alpha_s(\mu) \right) \right] \right\}. \tag{1.1}
\]

The first exponent in the above expression resums soft and collinear corrections from the incoming partons \( a \) and \( b \) (quark-antiquark or gluon-gluon) while the second exponent controls the factorization scale, \( \mu_F \), dependence of the cross section. \( H_{ab} \) is the hard-scattering function while \( S_{ab} \) is the soft function describing noncollinear soft gluon emission. The renormalization group evolution of the soft function is controlled by the soft anomalous dimension, \( \Gamma_{S_{ab}} \) [15]. It is important to note that \( H_{ab} \), \( S_{ab} \), and \( \Gamma_{S_{ab}} \) are matrices in the space of color structures of the process [15, 33, 34]. In the next section we will present explicit expressions for the new two-loop results for the soft anomalous dimension matrices \( \Gamma_{S_{qq}} \), for the \( qq \to t\bar{t} \) channel, and \( \Gamma_{S_{gg}} \), for the \( gg \to t\bar{t} \) channel. It is these new ingredients that allow us to complete the NNLL resummation in our formalism (for other approaches see Refs. [25, 26, 27, 30, 32] and the discussion in Section 5).

The resummed cross section, Eq. (1.1) can be expanded at fixed order in \( \alpha_s \) to NLO, NNLO, etc., and inverted back to momentum space, see e.g. Refs. [13, 33, 34, 35]. At each order in \( \alpha_s \), one encounters plus-distribution terms of the form \( \ln^k \left( s_4/m^2 \right) / s_4 \), where \( m \) is the top quark mass and, for the \( n \)-th order corrections, the power of the logarithm, \( k \), can range from the
leading value of $2n - 1$ down to the lowest value of 0. Thus at NLO $k = 1$ or 0, while at NNLO $k$ can take the values 3, 2, 1, 0. From NLL resummation one can determine the coefficients of both, $k = 1, 0$, powers of the logarithms at NLO, but only the powers $k = 3, 2, 1$ at NNLO (determining the NNLO $k = 1$ term requires matching with NLO). Partial results for the $k = 0$ term at NNLO were provided in Ref. [13] and also used in [14]. From NNLL resummation one can in addition fully determine the $k = 0$ term at NNLO.

In the following section we present the soft anomalous dimension matrices for the $q \bar{q} \rightarrow t \bar{t}$ and $gg \rightarrow t \bar{t}$ channels at one and two loops. In Section 3 we use the NNLL resummation to obtain approximate NNLO results for the total $t \bar{t}$ cross section and the top quark $p_T$ distribution in proton-antiproton collisions at the Tevatron. In Section 4 corresponding results are given for proton-proton collisions at LHC energies. A comparison with other approaches and conclusions are given in Section 5.

## 2 Soft anomalous dimension matrices for $t \bar{t}$ production

We begin with the result for the soft (cusp) anomalous dimension $\Gamma_S$ [22] for $e^+e^- \rightarrow t \bar{t}$, which is an integral part of the calculation for the soft anomalous dimension matrices $\Gamma_{Sqq}$ and $\Gamma_{Sgg}$ for $t \bar{t}$ hadroproduction. The calculations of soft anomalous dimensions involve diagrams with eikonal lines representing the top quarks. The eikonal diagrams are calculated in Feynman gauge in momentum space, and we use dimensional regularization with $d = 4 - \epsilon$ dimensions to isolate the ultraviolet (UV) poles of the diagrams. The soft anomalous dimension is then determined from the coefficients of the UV poles [22]. Writing $\Gamma_S = (\alpha_s/\pi)\Gamma_S^{(1)} + (\alpha_s/\pi)^2\Gamma_S^{(2)} + \cdots$, we have the one-loop expression

$$\Gamma_S^{(1)} = C_F \left[ -\frac{(1 + \beta^2)}{2\beta} \ln \left( \frac{1 - \beta}{1 + \beta} \right) - 1 \right] = -C_F [L_\beta + 1] \tag{2.1}$$

where $C_F = (N_c^2 - 1)/(2N_c)$, with $N_c = 3$ the number of colors; $\beta = \sqrt{1 - 4m^2/s}$, with $s$ the squared c.m. energy; and

$$L_\beta = \frac{1 + \beta^2}{2\beta} \ln \left( \frac{1 - \beta}{1 + \beta} \right). \tag{2.2}$$

The two-loop soft (cusp) anomalous dimension, determined from the UV poles of two-loop eikonal diagrams, is [22, 29]

$$\Gamma_S^{(2)} = \frac{K}{2} \Gamma_S^{(1)} + C_FC_A M_\beta \tag{2.3}$$

where $K = C_A(67/18 - \zeta_2) - 5n_f/9$, with $C_A = N_c$ and $n_f = 5$ the number of light-quark flavors. We have written the two-loop result $\Gamma_S^{(2)}$ in Eq. (2.3) in the form of a term which is a multiple of the one-loop soft anomalous dimension $\Gamma_S^{(1)}$ plus additional terms, denoted as $M_\beta$:

$$M_\beta = \frac{1}{2} + \frac{\zeta_2}{2} + \frac{1}{2} \ln^2 \left( \frac{1 - \beta}{1 + \beta} \right) - \frac{(1 + \beta^2)^2}{8\beta^2} \left[ \zeta_3 + \zeta_2 \ln \left( \frac{1 - \beta}{1 + \beta} \right) + \frac{1}{3} \ln^3 \left( \frac{1 - \beta}{1 + \beta} \right) + \ln \left( \frac{1 - \beta}{1 + \beta} \right) \text{Li}_2 \left( \frac{(1 - \beta)^2}{(1 + \beta)^2} \right) - \text{Li}_3 \left( \frac{(1 - \beta)^2}{(1 + \beta)^2} \right) \right]$$

3
\[ -\frac{(1 + \beta^2)}{4\beta} \left[ \zeta_2 - \zeta_2 \ln \left( \frac{1 - \beta}{1 + \beta} \right) + \ln^2 \left( \frac{1 - \beta}{1 + \beta} \right) - \frac{1}{3} \ln^3 \left( \frac{1 - \beta}{1 + \beta} \right) \\
+ 2 \ln \left( \frac{1 - \beta}{1 + \beta} \right) \ln \left( \frac{(1 + \beta)^2}{4\beta} \right) - \text{Li}_2 \left( \frac{(1 - \beta)^2}{(1 + \beta)^2} \right) \right]. \]

(2.4)

This result, first obtained in [22], is written in terms of logarithms, dilogarithms, and trilogarithms, and it provides a more explicit analytical expression than earlier work [36]. Note that as \( \beta \to 1, M_\beta \to (1 - \zeta_3)/2. \)

We can now proceed with the results for the two-loop soft anomalous dimension matrices for the partonic processes \( q\bar{q} \to t\bar{t} \) and \( gg \to t\bar{t}. \) The calculation involves the two-loop soft (cusp) anomalous dimension for all pairs of external lines in the process (cf. [22, 28, 29]) as well as graphs with gluons connecting three external lines (cf. [23, 27, 31]). We begin with top quark production through light quark annihilation,

\[ q(p_a) + \bar{q}(p_b) \to t(p_1) + \bar{t}(p_2). \]

(2.5)

We define the kinematical invariants

\[ s = (p_a + p_b)^2, \quad t_1 = (p_b - p_1)^2 - m^2, \quad u_1 = (p_a - p_1)^2 - m^2, \]

and \( s_4 = s + t_1 + u_1, \) where \( s_4 \) measures distance from partonic threshold. The calculations are performed in a color tensor basis consisting of singlet and octet exchange in the \( s \) channel,

\[ c_1 = \delta_{ab}\delta_{12}, \quad c_2 = T_F^c T_F^{a b} T_F^{1 2}. \]

(2.7)

Here the color indices for the incoming (light) quark and antiquark are \( a \) and \( b, \) respectively, and for the outgoing top quark and antiquark 1 and 2, respectively, and \( T_F^c \) are the generators of \( SU(3) \) in the fundamental representation.

The matrix for \( q\bar{q} \to t\bar{t} \) in this \( c_1, c_2 \) color basis is

\[ \Gamma_{S q\bar{q}} = \begin{bmatrix} \Gamma_{q\bar{q}11} & \Gamma_{q\bar{q}12} \\ \Gamma_{q\bar{q}21} & \Gamma_{q\bar{q}22} \end{bmatrix}. \]

(2.8)

At one loop:

\[ \Gamma_{q\bar{q}11}^{(1)} = -C_F [L_\beta + 1] = \Gamma_S^{(1)}, \]

\[ \Gamma_{q\bar{q}21}^{(1)} = 2 \ln \left( \frac{u_1}{t_1} \right), \]

\[ \Gamma_{q\bar{q}12}^{(1)} = \frac{C_F}{C_A} \ln \left( \frac{u_1}{t_1} \right), \]

\[ \Gamma_{q\bar{q}22}^{(1)} = C_F \left[ 4 \ln \left( \frac{u_1}{t_1} \right) - L_\beta - 1 \right] + \frac{C_A}{2} \left[ -3 \ln \left( \frac{u_1}{t_1} \right) + \ln \left( \frac{t_1 u_1}{s m^2} \right) + L_\beta \right]. \]

(2.9)

The result in Eq. (2.9) is somewhat different from the original in Ref. [15] because the original calculation used the axial gauge while Eq. (2.9) is in Feynman gauge. Of course this
does not affect the complete resummed expression because other terms in the resummed cross section compensate by also taking different forms in the two gauges. We note that the “11” element of the matrix is simply the cusp anomalous dimension, $\Gamma_S$.

At two loops:

\begin{align*}
\Gamma^{(2)}_{qq11} &= \frac{K}{2} \Gamma^{(1)}_{qq11} + C_F C_A M_\beta = \Gamma^{(2)}_S , \\
\Gamma^{(2)}_{qq21} &= \frac{K}{2} \Gamma^{(1)}_{qq21} + C_A N_\beta \ln \left( \frac{u_1}{t_1} \right) , \\
\Gamma^{(2)}_{qq12} &= \frac{K}{2} \Gamma^{(1)}_{qq12} - \frac{C_F}{2} N_\beta \ln \left( \frac{u_1}{t_1} \right) , \\
\Gamma^{(2)}_{qq22} &= \frac{K}{2} \Gamma^{(1)}_{qq22} + C_A \left( C_F - \frac{C_A}{2} \right) M_\beta . \quad (2.10)
\end{align*}

Here the term

\begin{equation}
N_\beta = \frac{1}{2} \ln^2 \left( \frac{1-\beta}{1+\beta} \right) - \frac{(1+\beta^2)}{4\beta} \left[ \ln^2 \left( \frac{1-\beta}{1+\beta} \right) + 2 \ln \left( \frac{1-\beta}{1+\beta} \right) \ln \left( \frac{(1+\beta)^2}{4\beta} \right) \right] - \text{Li}_2 \left( \frac{(1-\beta)^2}{(1+\beta)^2} \right) \quad (2.11)
\end{equation}

comes from graphs with gluons connecting three external lines, whose contribution were first calculated explicitly in \[27\]. Note that $N_\beta$ is just a subset of the terms of $M_\beta$, Eq. (2.4), so all analytical structures already appear in $M_\beta$, and that as $\beta \to 1$, $N_\beta \to 0$. The two-loop matrix, Eq. (2.10) is not proportional to the one-loop matrix, Eq. (2.9). This fact was first discussed in Ref. \[22\] and it is to be contrasted with the simple proportionality relation for the massless case that was found in Ref. \[16\].

We continue with the $gg$ channel:

\begin{equation}
g(p_a) + g(p_b) \to t(p_1) + \bar{t}(p_2) . \quad (2.12)
\end{equation}

We choose the following basis for the color factors:

\begin{equation}
c_1 = \delta^{ab} \delta_{12}, \quad c_2 = d^{abc} T_{12}^c, \quad c_3 = i f^{abc} T_{12}^c \quad (2.13)
\end{equation}

where $d^{abc}$ and $f^{abc}$ are the totally symmetric and antisymmetric $SU(3)$ invariant tensors, respectively. We define $s$, $t_1$, and $u_1$ for this channel as in Eq. (2.6).

The matrix for $gg \to t\bar{t}$ in this basis is

\begin{equation}
\Gamma_{S\,gg} = \begin{bmatrix}
\Gamma_{gg\,11} & 0 & \Gamma_{gg\,13} \\
0 & \Gamma_{gg\,22} & \Gamma_{gg\,23} \\
\Gamma_{gg\,31} & \Gamma_{gg\,32} & \Gamma_{gg\,22}
\end{bmatrix} . \quad (2.14)
\end{equation}

At one loop:

\begin{align*}
\Gamma^{(1)}_{gg\,11} &= -C_F [L_\beta + 1] = \Gamma^{(1)}_S , \\
\Gamma^{(1)}_{gg\,31} &= 2 \ln \left( \frac{u_1}{t_1} \right) ,
\end{align*}
\[ \Gamma_{gg13}^{(1)} = \ln \left( \frac{u_1}{t_1} \right), \]
\[ \Gamma_{gg22}^{(1)} = -C_F [L\beta + 1] + \frac{C_A}{2} \left[ \ln \left( \frac{t_1 u_1}{m^2 s} \right) + L\beta \right], \]
\[ \Gamma_{gg32}^{(1)} = \frac{N_c^2 - 4}{2 N_c} \ln \left( \frac{u_1}{t_1} \right), \]
\[ \Gamma_{gg23}^{(1)} = \frac{C_A}{2} \ln \left( \frac{u_1}{t_1} \right). \]

The expression in Eq. (2.15) is again somewhat different from the original in Ref. [15] because Eq. (2.15) is derived in Feynman gauge.

At two loops:
\[ \Gamma_{gg11}^{(2)} = \frac{K}{2} \Gamma_{gg11}^{(1)} + C_F C_A M\beta = \Gamma_S^{(2)}, \]
\[ \Gamma_{gg31}^{(2)} = \frac{K}{2} \Gamma_{gg31}^{(1)} + C_A \ln \left( \frac{u_1}{t_1} \right), \]
\[ \Gamma_{gg13}^{(2)} = \frac{K}{2} \Gamma_{gg13}^{(1)} - \frac{C_A}{2} \ln \left( \frac{u_1}{t_1} \right), \]
\[ \Gamma_{gg22}^{(2)} = \frac{K}{2} \Gamma_{gg22}^{(1)} + C_A \left( C_F - \frac{C_A}{2} \right) M\beta, \]
\[ \Gamma_{gg32}^{(2)} = \frac{K}{2} \Gamma_{gg32}^{(1)}, \]
\[ \Gamma_{gg23}^{(2)} = \frac{K}{2} \Gamma_{gg23}^{(1)}. \]

The expressions in Eqs. (2.10) and (2.16) are different from the corresponding ones in [27] due to different definitions and formalism.

As was the case for the \( q\bar{q} \) channel, we note that for the \( gg \) channel the two-loop matrix, Eq. (2.16) is not proportional to the one-loop matrix, Eq. (2.15).

With the two-loop soft anomalous dimension matrices at hand we achieve NNLL accuracy in the resummed cross section, Eq. (1.1). Expanding the resummed cross section to NNLO we then calculate approximate NNLO cross sections and transverse momentum distributions for top quarks at the Tevatron and the LHC.

3 Top cross section and \( p_T \) distribution at the Tevatron

We now provide a detailed phenomenological study of top quark production at the Tevatron collider, including the total \( t\bar{t} \) cross section and the top quark \( p_T \) distribution. We present NLO and approximate NNLO calculations for these quantities. The NNLO approximate results are computed by adding the NNLO soft-gluon corrections (derived from NNLL resummation) to the exact NLO quantities. The total and differential cross sections depend on the factorization scale, \( \mu_F \), and the renormalization scale, \( \mu_R \). These two scales are often set equal to each other and denoted simply as \( \mu \), but they are in principle independent.
Figure 1: The NLO and approximate NNLO cross section for $t\bar{t}$ production at the Tevatron with $\sqrt{S} = 1.96$ TeV and MSTW2008 NNLO pdf.

### 3.1 $t\bar{t}$ cross section at the Tevatron

In Fig. 1 we plot the cross section for top-antitop production in proton-antiproton collisions at the Tevatron over a top quark mass range $165 \leq m \leq 180$ GeV at a factorization and renormalization scale $\mu = m$. The exact NLO and the approximate NNLO cross sections are shown. The enhancement from the NNLO soft-gluon corrections is 7.8%. Here we have used the MSTW2008 NNLO parton distribution functions (pdf) [37]. We will use these pdf for our calculations throughout this paper except where noted otherwise.

Table 1 lists the values for the NNLO approximate cross section at the Tevatron for top quark masses between 170 GeV and 175 GeV. There are two kinds of theoretical uncertainties associated with the calculation: dependence on the factorization/renormalization scale, and uncertainties from the parton densities.

The scale dependence of the cross section for $m = 173$ GeV is plotted in Fig. 2 over a range of two orders of magnitude, $0.2 \leq \mu/m \leq 10$. It is clear that at leading order (LO) the cross section is strongly dependent on the choice of scale, varying by a factor of 5.45 between maximum and minimum values in the range shown. The NLO corrections significantly stabilize the LO variation: the NLO cross section varies by a factor of 1.61. The NNLO soft-gluon corrections further reduce the scale dependence: the NNLO approximate cross section varies by a factor of only 1.18. The improvement provided by the NNLO corrections is even more impressive if one considers only the variation $0.5 \leq \mu/m \leq 2$ as traditionally used to estimate errors. For this range the LO cross section varies by a factor of 1.85, the NLO cross section by 1.16, while the NNLO approximate cross section by a factor of only 1.034.
Table 1: The NNLO approximate $t\bar{t}$ production cross section in pb in $p\bar{p}$ collisions at the Tevatron with $\sqrt{S} = 1.96$ TeV and in pp collisions at the LHC with $\sqrt{S} = 7$ TeV and 14 TeV. We set $\mu = m$ and use the MSTW2008 NNLO pdf [37].

| $m$ (GeV) | Tevatron | LHC 7 TeV | LHC 14 TeV |
|-----------|-----------|------------|------------|
| 170       | 7.78      | 179        | 998        |
| 171       | 7.54      | 173        | 972        |
| 172       | 7.31      | 168        | 946        |
| 173       | 7.08      | 163        | 920        |
| 174       | 6.87      | 158        | 896        |
| 175       | 6.66      | 154        | 873        |

For a top quark mass of 173 GeV, the NLO cross section is $6.57^{+0.27}_{-0.66}$ pb and the NNLO approximate cross section is

$$\sigma_{t\bar{t}}^{\text{NNLOapprox}}(m = 173 \text{ GeV}, 1.96 \text{ TeV}) = 7.08^{+0.00+0.36}_{-0.24-0.27} \text{ pb}.$$  

Here the first uncertainty is from scale variation over $0.5 \leq \mu/m \leq 2$ and the second is from the MSTW2008 NNLO pdf errors at 90% C.L. (to be conservative, we do not use the smaller 68% C.L. pdf errors). At NLO the scale uncertainty is bigger than that from the pdf, but at NNLO the scale uncertainty is much smaller than the pdf one. In fact the scale uncertainty at NNLO is about four times smaller than that at NLO, again highlighting the dramatic reduction of scale dependence provided by the higher-order corrections. Adding the scale and pdf errors in quadrature, the NNLO approximate result is $7.08 \pm 0.36$ pb, i.e., we have a $\pm 5.1\%$ total uncertainty, which is to be contrasted with a much larger ($+6.6\% -10.7\%$) total error (in quadrature) at NLO.

One can also study the dependence of the cross section separately on the factorization scale and the renormalization scale. This can be important because in some cases setting $\mu_F$ equal to $\mu_R$ may give a smaller uncertainty than from varying the scales independently. In Fig. 3 we plot the scale dependence of the cross section for $m = 173$ GeV in three different ways at NLO (top plot) and approximate NNLO (bottom plot). The first way is to set $\mu = \mu_F = \mu_R$ and vary this common scale, exactly as we did in Fig. 2. The second way is to vary the factorization scale $\mu_F$ while keeping the renormalization scale fixed at $\mu_R = m$. The third way is to vary $\mu_R$ while keeping $\mu_F = m$. It is clear from the top plot that varying $\mu_F$ and $\mu_R$ independently over the range $m/2$ and $2m$ does not give a wider range of cross section values than varying the common scale $\mu = \mu_F = \mu_R$. In fact as can be seen from the figure this holds true for a very wide range of scale variation. We also note that setting $\mu_F = m/2$ and $\mu_R = 2m$ or setting $\mu_R = m/2$ and $\mu_F = 2m$ still gives a smaller variation than varying the common scale $\mu = \mu_F = \mu_R$ between $m/2$ and $2m$. Therefore the NLO theoretical uncertainty that we provided above from scale variation is not increased by separately varying $\mu_F$ and $\mu_R$. For the approximate NNLO cross section in the bottom plot of Fig. 3 we see that the variation with $\mu = \mu_F$ and $\mu_R = m$ affects the upper uncertainty (which was stated before as $+0.00$) and this new upper uncertainty is $+0.20$. However the lower uncertainty ($-0.24$) is unaffected. So the result for the approximate
Figure 2: The scale dependence of the $t\bar{t}$ cross section at the Tevatron with $\sqrt{S} = 1.96$ TeV and $m = 173$ GeV.

Figure 3: The $\mu_F$ and $\mu_R$ dependence of the $t\bar{t}$ cross section at the Tevatron with $\sqrt{S} = 1.96$ TeV and $m = 173$ GeV. The top plot is at NLO and the bottom is at approximate NNLO accuracy.
NNLO cross section for $m = 173$ GeV with the scale uncertainty from independent $\mu_F$ and $\mu_R$ variation can be written as $7.08^{+0.36}_{-0.24} \pm 0.27$ pb. Finally, we note that not only is the scale variation with $\mu = \mu_F = \mu_R$ greatly reduced in going from NLO to approximate NNLO but so is the separate $\mu_F$ variation and the separate $\mu_R$ variation.

The MSTW2008 parton densities are the only ones available at NNLO and so we use them for our best predictions. It is interesting nevertheless to see if the results change significantly using the new CT10 pdf [38], which are at NLO, and the pdf errors associated with them. Using CT10 pdf we find a NLO cross section for $m = 173$ GeV of $6.81^{+0.45}_{-0.35} \pm 0.24$ pb, and an approximate NNLO cross section of $7.38^{+0.45}_{-0.25} \pm 0.32$ pb, where the first uncertainty is from scale variation (with $\mu_F$ and $\mu_R$ independently varied) and the second is from the pdf errors. We thus find both a larger cross section and a larger uncertainty with CT10 pdf than with MSTW2008 NNLO pdf.

### 3.2 Top quark $p_T$ distribution at the Tevatron

The top quark transverse momentum distribution at the Tevatron with $m = 173$ GeV is plotted in Figs. 4 and 5 using the MSTW2008 NNLO pdf. Fig. 4 shows the differential distribution $d\sigma/dp_T$ over a range $0 \leq p_T \leq 300$ GeV. Both NLO and NNLO approximate results are shown for three different scale choices, $\mu = m/2$, $m$, and $2m$. The integrated $p_T$ distribution gives the same result for the total cross section as found in the previous subsection, which provides a good consistency check of the calculation. The scale variation of the $p_T$ distribution at NNLO is again significantly smaller than at NLO. The NNLO soft-gluon corrections enhance the NLO
result but the shape is similar.

Figure 5 presents the top quark $p_T$ distribution in a logarithmic plot that makes it easier to see $d\sigma/dp_T$ at high $p_T$ values. Results are now shown up to a $p_T$ of 500 GeV. In Fig. 4 the central value for the scale was taken to be $\mu = m$ as for the total cross section, and the scale variation was around that central value. Another possible scale choice for the top quark $p_T$ distribution is the transverse mass $m_T$, defined by $m_T = (p_T^2 + m^2)^{1/2}$. In Fig. 5 we show our NLO and approximate NNLO results for both $\mu = m$ and $\mu = m_T$. We find that the choice of scale, $m$ versus $m_T$, makes very little difference even for high $p_T$ of 500 GeV - the curves are practically indistinguishable.

Joint threshold and recoil resummation for the $p_T$ distribution (at NLL accuracy only) has been studied in [39]. The effect of recoil is entirely negligible except at extremely high $p_T$ ($\sim 800$ GeV and above) so we do not consider it further.

4 Top cross section and $p_T$ distribution at the LHC

We continue with a detailed phenomenological study of top quark production in proton-proton collisions at the LHC. We present results for the current LHC energy of 7 TeV and the future (design) energy of 14 TeV, and also a few results at 10 TeV.
4.1 $t\bar{t}$ cross section at the LHC

In Fig. 6 we plot the NLO and approximate NNLO cross section for top-antitop production at the LHC at 7 TeV energy over a top quark mass range $165 \leq m \leq 180$ GeV at a factorization and renormalization scale $\mu = m$ using the MSTW2008 NNLO pdf. The enhancement from the NNLO soft-gluon corrections is 7.6%. Table 1 lists the values for the NNLO approximate cross section at the LHC at an energy of 7 TeV for top quark masses between 170 GeV and 175 GeV.

The scale dependence of the cross section for $m = 173$ GeV is plotted in Fig. 7 over a range of two orders of magnitude, $0.2 \leq \mu/m \leq 10$. Again, at LO the cross section is strongly dependent on the choice of scale, varying by a factor of 4.64 between maximum and minimum values in the range shown. The NLO corrections stabilize the LO variation: the NLO cross section varies by a factor of 1.85. The NNLO soft-gluon corrections further reduce the scale dependence: the NNLO approximate cross section varies by a factor of 1.43. The improvement from the NNLO corrections is again more impressive if one considers only the traditional variation $0.5 \leq \mu/m \leq 2$. For this range the LO cross section varies by a factor of 1.75, the NLO cross section by 1.27, while the NNLO approximate cross section by a factor of only 1.08.

For a top quark mass of 173 GeV, the NLO cross section is $152^{+16+8}_{-19-9}$ pb and the NNLO approximate cross section is

$$\sigma_{t\bar{t}}^{\text{NNLOapprox}}(m = 173 \text{GeV}, 7 \text{ TeV}) = 163^{+7+9}_{-5-9} \text{ pb}$$

(4.1)
where the first uncertainty is from scale variation over $0.5 \leq \mu/m \leq 2$ and the second is from the MSTW2008 NNLO pdf errors at 90% C.L. At NLO the scale uncertainty is about twice as big as the pdf one, but at NNLO it is significantly smaller. The scale uncertainty at NNLO is about three times smaller than that at NLO. Adding the scale and pdf errors in quadrature the NNLO approximate result is $163^{+11}_{-10}$ pb, i.e. we have a $+7.0\% -6.3\%$ total uncertainty, which is to be contrasted with a much larger $(+11.8\% -13.8\%)$ total error at NLO.

We also study the dependence of the cross section separately on the factorization scale and the renormalization scale. In Fig. 8 we plot the scale dependence of the cross section in three different ways at NLO (top plot) and approximate NNLO (bottom plot). The first way is to set $\mu = \mu_F = \mu_R$ and vary this common scale, as we did in Fig. 7. The second way is to vary $\mu_F$ while keeping $\mu_R = m$, and the third way is to vary $\mu_R$ while keeping $\mu_F = m$. From the top plot we see that varying $\mu_F$ and $\mu_R$ independently over the range $m/2$ and $2m$ does not give a wider range of cross section values than varying the common scale $\mu = \mu_F = \mu_R$, and this actually holds true for nearly the entire wide range of scale variation shown in the plot. We also find that setting $\mu_F = m/2$ and $\mu_R = 2m$ or setting $\mu_R = m/2$ and $\mu_F = 2m$ still gives a smaller variation than varying the common scale $\mu = \mu_F = \mu_R$ between $m/2$ and $2m$. Therefore the NLO theoretical uncertainty from scale variation provided previously is not increased by separately varying $\mu_F$ and $\mu_R$. For the approximate NNLO cross section in the bottom plot of Fig. 8 we also see that the independent variation of $\mu_F$ and $\mu_R$ does not affect the uncertainty that we wrote previously. Finally, we note that the separate $\mu_F$ variation and $\mu_R$ variation are reduced when going from NLO to approximate NNLO.

Again we can check if the results change significantly using the CT10 pdf, which are at
NLO. Using CT10 pdf we find a NLO cross section at $m = 173$ GeV of $150^{+18}_{-20}^{+11}$ pb, and an approximate NNLO cross section of $162^{+9}_{-7}^{+12}$ pb, so the results are very similar to those with MSTW2008 NNLO pdf.

For reference, the cross section at a possible future LHC energy of 10 TeV is plotted in Fig. 9 using the MSTW2008 NNLO pdf. For a top quark mass of 173 GeV, we find a NLO cross section of $385^{+41}_{-45}^{+17}$ pb, while at NNLO

$$\sigma_{tt}^{\text{NNLOapprox}}(m = 173 \text{ GeV}, 10 \text{ TeV}) = 415^{+17}_{-21}^{+18} \text{ pb}. \quad (4.2)$$

The cross section for the design LHC energy of 14 TeV is plotted in Fig. 10 using the MSTW2008 NNLO pdf. The enhancement from the NNLO soft-gluon corrections is 8.0%. Table 1 lists the values for the NNLO approximate cross section at 14 TeV LHC energy for top quark masses between 170 GeV and 175 GeV. The NLO cross section for a top quark mass of 173 GeV is $852^{+91}_{-93}^{+30}$ pb and the approximate NNLO cross section is

$$\sigma_{tt}^{\text{NNLOapprox}}(m = 173 \text{ GeV}, 14 \text{ TeV}) = 920^{+50}_{-39}^{+33} \text{ pb}. \quad (4.3)$$

Again we observe a significant decrease in scale dependence at NNLO relative to NLO, and also note that separate variation of $\mu_F$ and $\mu_R$ does not increase the uncertainty. The pdf uncertainties at this high energy are much smaller than the scale variation at NLO, and somewhat relatively smaller at NNLO. Adding the scale and pdf errors in quadrature the NNLO approximate result is $920^{+60}_{-52}$ pb, i.e. we have a $+6.5\% -5.7\%$ total uncertainty, which is to be contrasted with a much larger ($+11.2\% -11.6\%$) total uncertainty at NLO.
Figure 9: The cross section for $t\bar{t}$ production at the LHC with $\sqrt{S} = 10$ TeV and MSTW2008 NNLO pdf.

Figure 10: The cross section for $t\bar{t}$ production at the LHC with $\sqrt{S} = 14$ TeV and MSTW2008 NNLO pdf.
4.2 Top quark $p_T$ distribution at the LHC

The transverse momentum distribution of the top quark with $m = 173$ GeV at the LHC at 7 TeV energy is plotted in Figs. 11 and 12 using the MSTW2008 NNLO pdf. Fig. 11 shows NLO and approximate NNLO results for the differential distribution $d\sigma/dp_T$ over a range $0 \leq p_T \leq 350$ GeV for three different scale choices, $\mu = m/2$, $m$, and $2m$. The scale variation of the $p_T$ distribution at NNLO is much smaller than that at NLO.

Figure 12 presents the results for $d\sigma/dp_T$ in a logarithmic plot for high $p_T$ values up to 1000 GeV, using both $\mu = m$ and $\mu = m_T$, where again $m_T$ is the transverse mass. At very high $p_T$ the NNLO approximate corrections become increasingly more significant and begin to change the shape of the distribution relative to NLO. This is not unexpected since the soft-gluon corrections are large near partonic threshold, which is dominant at high $p_T$. The change of shape is more pronounced with the choice $\mu = m$ than it is with $\mu = m_T$.

The $p_T$ distribution of the top quark with $m = 173$ GeV at the LHC at 14 TeV energy is plotted in Figs. 13 and 14. Fig. 13 shows NLO and approximate NNLO results over a range $0 \leq p_T \leq 400$ GeV for three different scale choices, $\mu = m/2$, $m$, and $2m$. Again, the scale variation of the $p_T$ distribution at NNLO is much smaller than that at NLO.

Figure 14 presents the results for $d\sigma/dp_T$ in a logarithmic plot for high $p_T$ values up to 1500 GeV, using $\mu = m$ and $\mu = m_T$. The NNLO soft-gluon corrections provide a significant enhancement and change the shape of the NLO distribution at very high $p_T$. Again, the change in shape is larger with the choice $\mu = m$ than it is with $\mu = m_T$.

5 Comparison with other approaches and Conclusions

In this paper we have resummed the soft-gluon logarithms in top quark production to NNLL accuracy. This work directly extends the earlier NLL resummation in Ref. [15] and the further work in [33, 34] and later in [13, 14]. To achieve NNLL (NLL) accuracy, it is necessary to derive the soft anomalous dimension matrix at two (one) loops for each partonic process. At NLL and NNLL the color structure of the hard scattering enters the resummation in a non-trivial way. The soft anomalous dimension matrices are explicitly dependent on the kinematical variables $s, t_1, u_1$, and the resummation involves these quantities and logarithms of $s_4$, where $s_4 = s + t_1 + u_1$ measures distance from partonic threshold. Thus this is a fully differential calculation and the formalism in this paper has been used to calculate not only total cross sections but also differential cross sections, such as transverse momentum distributions. Approximate NNLO differential cross sections are extracted from the resummation (higher-order contributions beyond NNLO are small, see e.g. Ref. [35]). The NNLO expansion avoids the need for prescriptions to deal with Landau-pole divergences in the resummation, and we prefer to take this approach since the numerical discrepancies between different prescriptions are larger than the corrections beyond NNLO (see e.g. discussion in [33, 14]).

There also exist formalisms of resummation and finite-order expansions for the total cross section only [40] that are calculationally simpler, and only involve the variable $\beta = \sqrt{1 - 4m^2/s}$. Logarithms of $\beta$ have been resummed at NLL in [40, 31] and at (partial) NNLL in [12] (Ref. [42] made an incorrect assumption about the two-loop terms which, as later understood, is not valid). This approach does not, however, involve the exact differential kinematics and hence
numerical deviations from the exact kinematics-sensitive result may appear. Furthermore this approach is inapplicable to $p_T$ or other differential distributions, so it is limited in scope. For further discussion of the differences see also Ref. [14] and [30]. More recently, complete NNLL results in logarithms of $\beta$ have appeared in Ref. [25] using soft-collinear and non-relativistic effective theory, and in Ref. [26] using resummation in moment space. Threshold expansions to NNLO for the total cross section from this $\ln \beta$ resummation have recently appeared in [43, 44]. Again, all these results are for total cross sections only, based on expansions in $\beta$. It is important to note that the terminology “NLL” and “NNLL” means different things in the approaches of Refs. [25, 26, 40, 41, 42, 43, 44] than it does in the differential-level formalism of Refs. [13, 14, 15, 33, 34] and of this paper because different types of logarithms are resummed.

Another differential-level formalism that has recently appeared [30, 45] is based on soft-collinear effective theory and heavy-quark effective theory. While the resummation in [13, 14, 15, 33, 34] and this paper is done in moment space, in [30] it is performed in momentum space. The total cross section and invariant mass distribution at NNLL have been presented in [30]. The total cross section results in [30] are quite different from those in this paper. One major reason for the difference is the different choice of kinematics, as we describe below.

In Refs. [33, 34, 13, 14] (based on the formalism of [15]) results were provided in both single-particle-inclusive (1PI) and pair-invariant-mass (PIM) kinematics. The kinematics ambiguity was studied in detail in [34] and found to be an important source of uncertainty. In 1PI kinematics the soft-gluon logarithms are of the form $[\ln^k(s_4/m^2)/s_4]_+$ and the soft-gluon corrections to the double differential cross section, $d^2\sigma/(dt_1du_1)$, are calculated. In PIM kinematics, the soft logarithms are of the form $[\ln^k(1-z)/(1-z)]_+$ with $z = M^2/s$, and $z \to 1$ near threshold, where $M^2$ is the $t\bar{t}$ pair mass squared. In PIM kinematics, the soft gluon corrections to the double differential cross section, $d^2\sigma/(dM^2d\cos \theta)$, where $\theta$ is the scattering angle in the partonic center-of-mass frame, are calculated. The cross section in PIM kinematics was found to be smaller than the 1PI result. The results in Refs. [33, 34] were based on NLL resummation and were later improved by adding subleading terms [13, 14]. The kinematics ambiguity was thus reduced in [13, 14]. Still it was shown in [13] that the PIM kinematics gives large negative results at NNLO for the $gg$ channel at LHC energies (for $t\bar{t}$ production at the LHC, the $gg$ channel is by far dominant over the $q\bar{q}$ channel). These negative corrections are deemed unphysical since already at NLO the PIM approximation for the corrections does not reproduce well the exact NLO result while the 1PI result is a much better approximation (detailed graphs for the partonic scaling functions in 1PI and PIM kinematics were shown in [34] and also [13]).

In the present paper we have thus used 1PI kinematics. In contrast, Ref. [30] uses a modified PIM kinematics. Although the modified PIM kinematics of Ref. [30] produces less negative results than PIM in [34] and [13], the overall NNLO contribution in modified PIM is still negative. This explains why both the NNLL resummed cross section and the NNLO approximate cross section with modified PIM in [30] is less than the NLO cross section at $\mu = m$ for both Tevatron and LHC energies. This is in sharp contrast to the 1PI results here and in all our previous calculations (at both NLL and NNLL accuracy) where the NNLO soft-gluon corrections are found to provide a positive enhancement of the NLO cross section. The 1PI kinematics provides an excellent approximation as evidenced by the fact that the NLO approximate 1PI corrections from the expansion of the resummed cross section account for well over 98% (up to 99.8%) of the exact NLO corrections in the $gg$ channel (with $\mu = m$) at both Tevatron and
LHC energies. This is a far better agreement than can be attained with PIM or modified PIM
kinematics. We thus remain of the opinion that the results in [30] do not accurately reflect the
true contribution of soft-gluon corrections.

It is also interesting to compare the results in this paper with our previous results in [13, 14].
Although NNLL resummation requires calculation of the two-loop soft anomalous dimension
matrices as presented in this paper, it was argued in [13, 14] that the numerical contribution
of this matrix at two loops to the cross section is expected to be small. In [13, 14] many of
the terms beyond NLL were already included in the calculation and it was argued based on the
study of the scaling functions in 1PI and PIM kinematics that these additional subleading terms
were relatively dominant. Now that the full two-loop NNLL terms are known it is important to
revisit the validity of this argument. We find that indeed the new two-loop terms from the soft
anomalous dimension matrices contribute very little to the total cross section, and hence the
argument was valid and the results in [13, 14] were robust. For example, using the MSTW2008
NNLO pdf [37] the calculation at the accuracy of Ref. [14] for the top quark cross section at the
LHC at 7 TeV gives 165 pb, while in this paper we find 163 pb based on NNLL resummation.
The difference between the two numbers is very small compared with the overall theoretical
uncertainty. Any differences in the numbers provided in [13, 14], and the present work are
overwhelmingly due to the use of different pdf and only to a rather small extent due to the
different theoretical accuracy.

To conclude, we have shown in this paper that the top quark cross section and trans-
verse momentum distribution receive significant enhancements from soft-gluon corrections at
NNLO. These corrections have been resummed at NNLL accuracy by calculating the two-loop
soft anomalous dimension matrices for the partonic processes. Approximate NNLO total and
differential cross sections have been derived from the NNLL resummed result. The NNLO soft-
gluon corrections enhance the total cross section and the $p_T$ distribution and greatly reduce the
theoretical uncertainty from scale variation. The pdf uncertainty of the cross section has also
been presented. Our NNLL resummation formalism can be used to calculate other differential
distributions of interest, such as the top quark rapidity distribution. This will be a topic of
future work.
